Tectonic Setting

Long, well-documented history of large/great EQs.

The South America subduction zone has both the shallow dip and deep coupled-uncoupled transition (~50 km) capable of producing very large EQs.

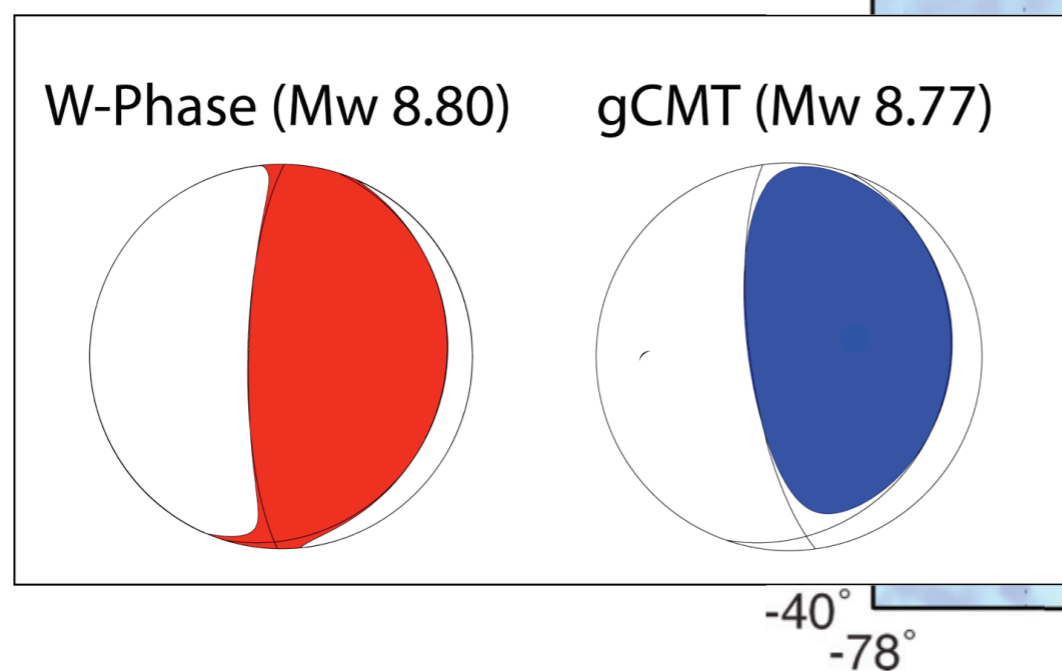

Tectonic Setting

Interface south of epicenter = South Chile Seismic Gap (Ruegg et al., 2009) - had not slipped since 1835.

Region to north partly failed in 1906, '28 and '85.

2010-02-27: Maule EQ, M_w 8.8, ~400 km rupture along-strike. At the time, 5th largest in instrumental era.

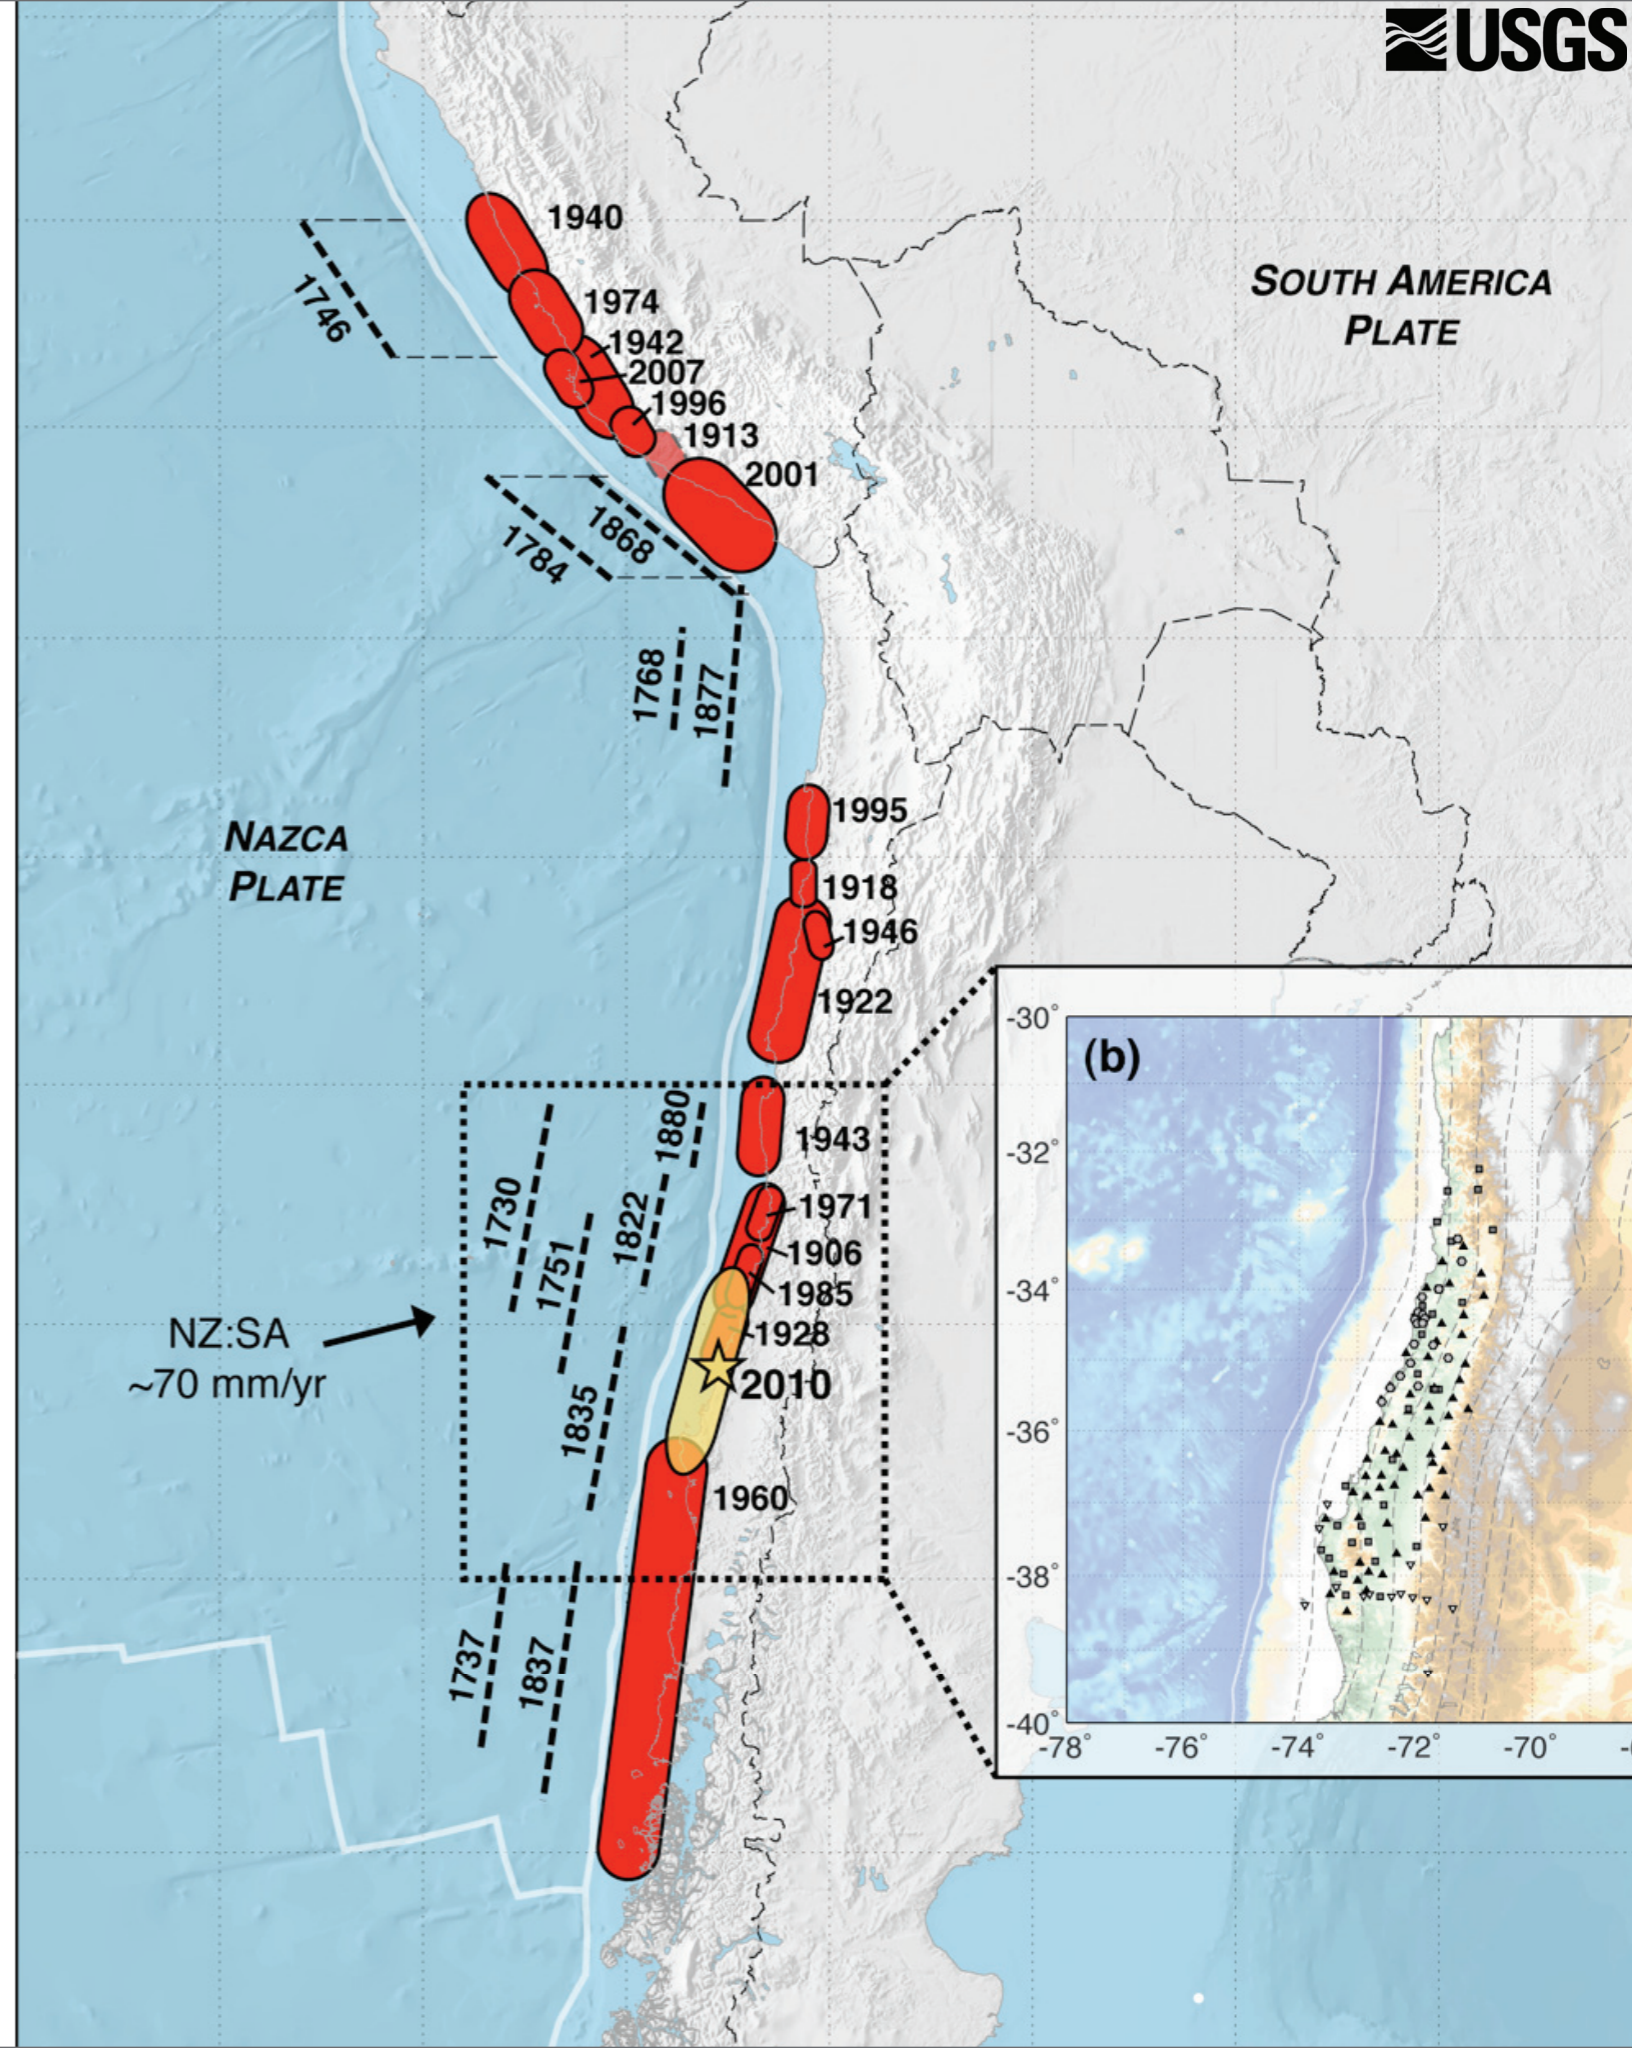

Maule Response

160 mostly broadband sensors deployed as the International Maule Aftershock Deployment (IMAD) temporary network; an international collaboration involving:

- Chilean Universities
- IRIS, USA
- INSU, CNRS, France
- GFZ, Germany
- U. of Liverpool, UK

Data open-access following their collection (most stations operated for ~9 months).

30,000 events automatically located with PA-HYDRA, an offline module mimicking NEIC's realtime data processing system.

We have relocated the highest quality ~10% of these events, and performed moment tensor analyses on the largest ~500.

Other analyses of the IMAD data include:

- Lange et al. (2012): automatically picked, 6 month catalog, 20,000+ aftershocks.
- Rietbrock et al. (2012): automatically picked, 2 month catalog, 30,000+ aftershocks. ~100 regional moment tensors.
- Agurto et al. (2012): MT catalog of 125 RMTs, 150 gCMTs.

System Status: 

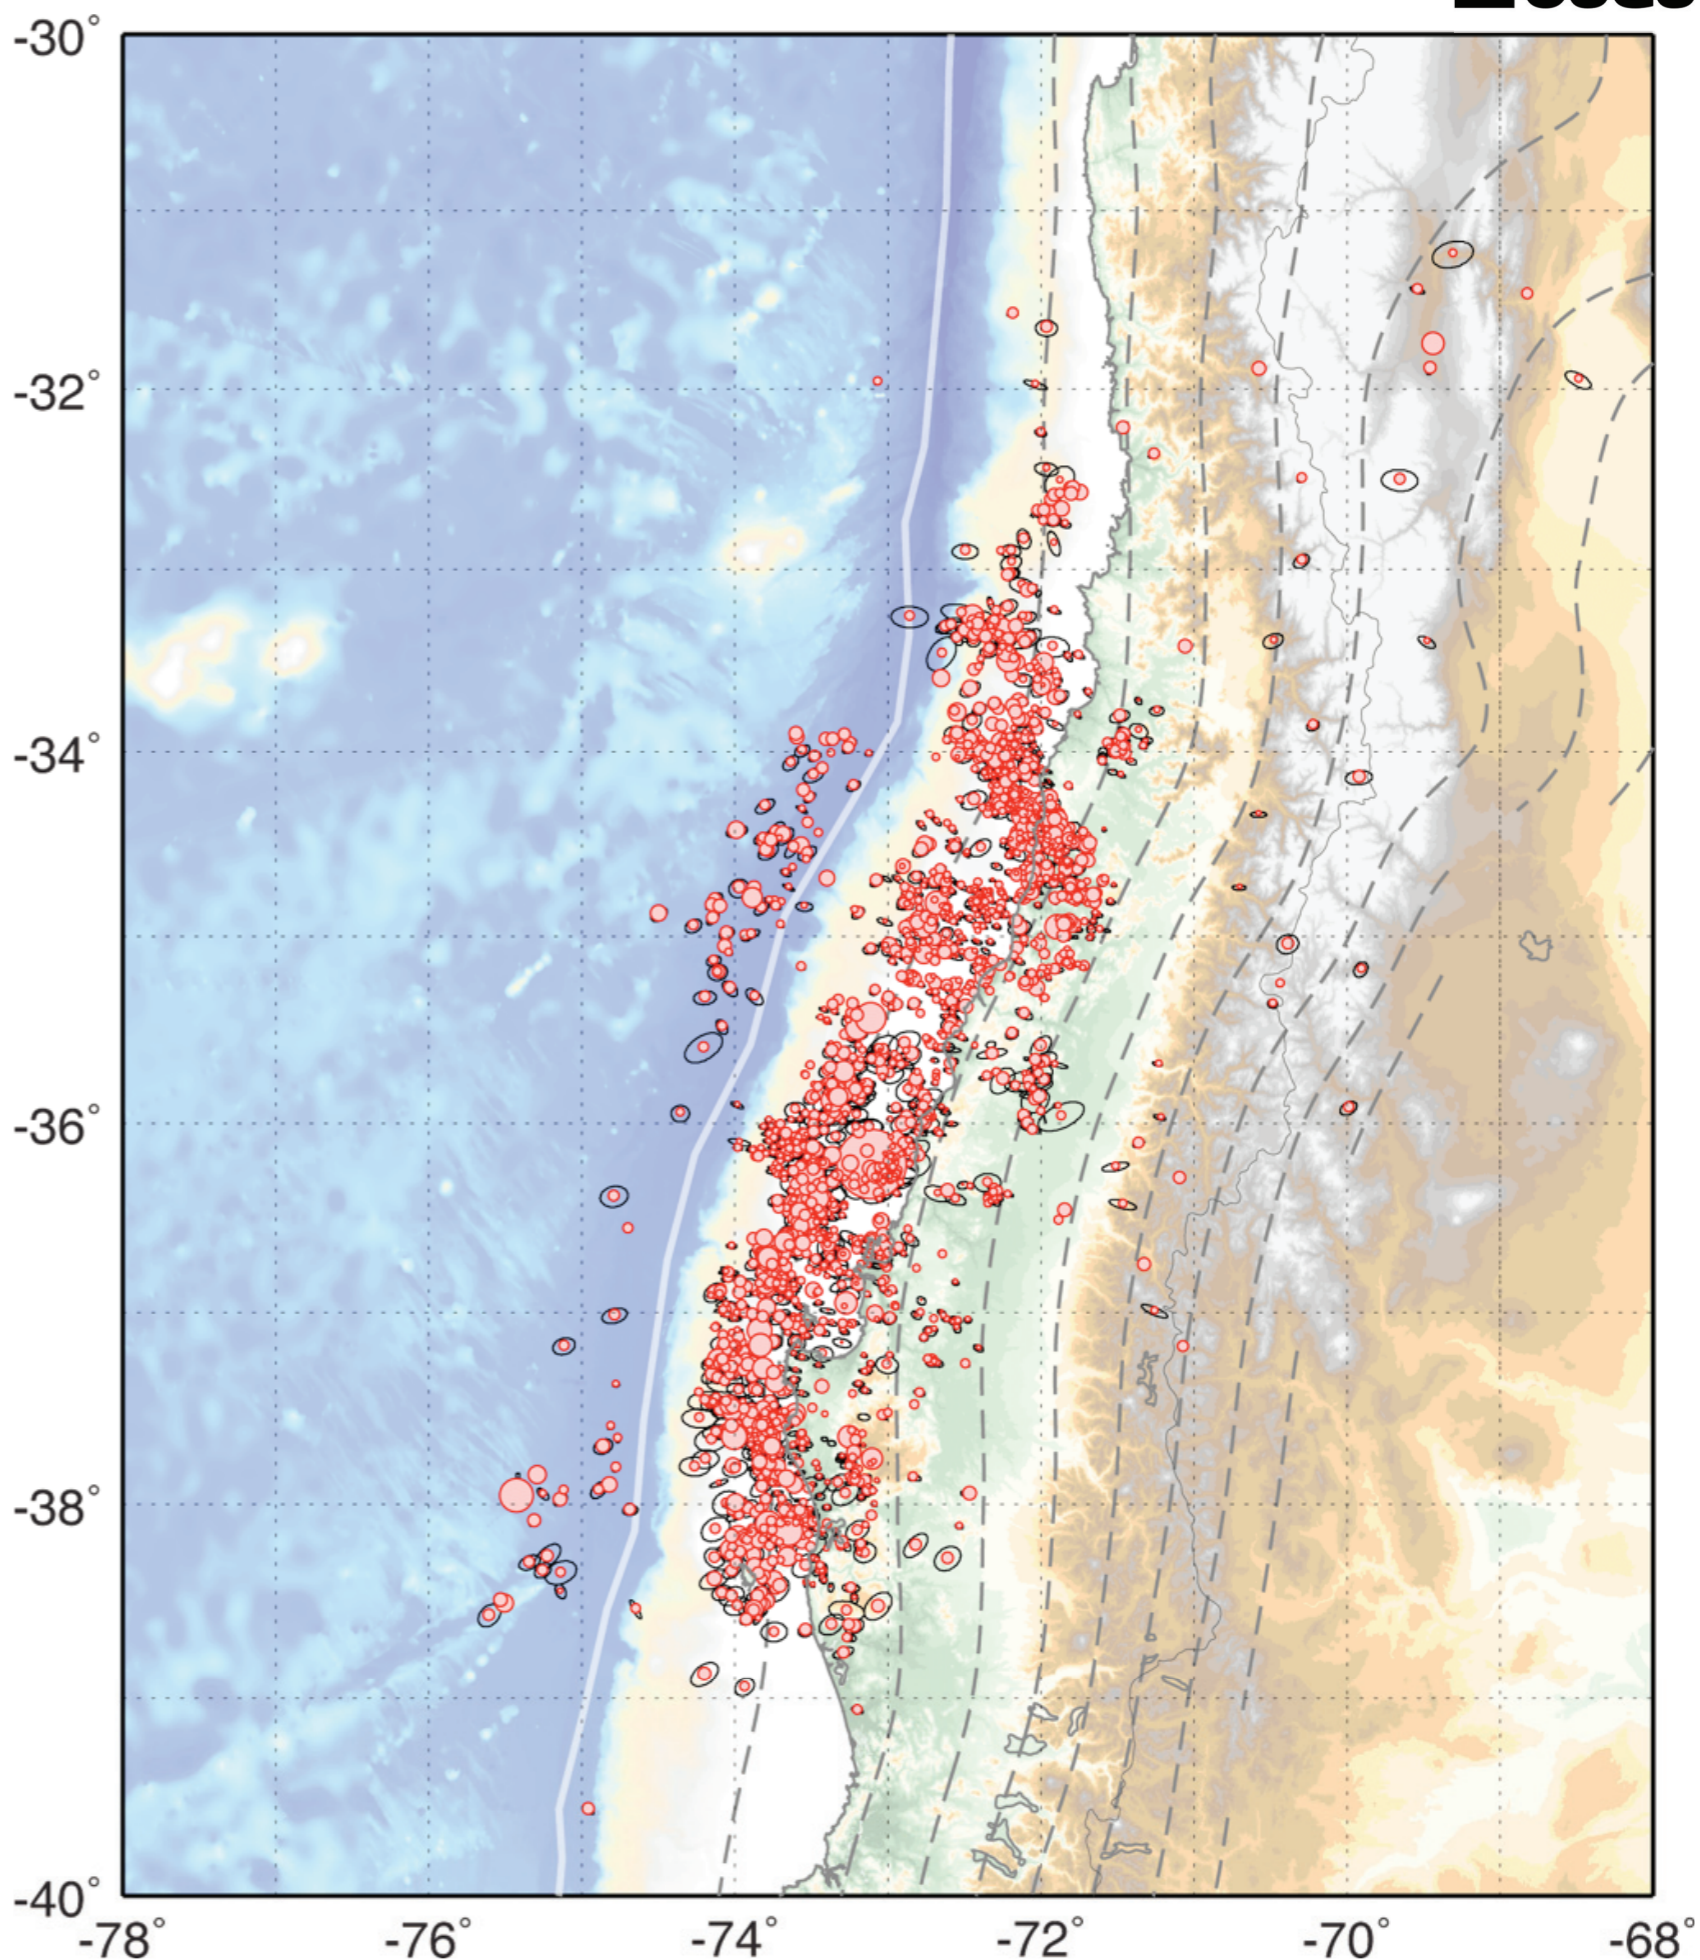

Relocated Aftershocks

2,500 events, relocated using a multiple event location approach (Hypocentral Decomposition).

==> High-precision relative and absolute locations.

Horizontal uncertainty averages ± 2.8 km.

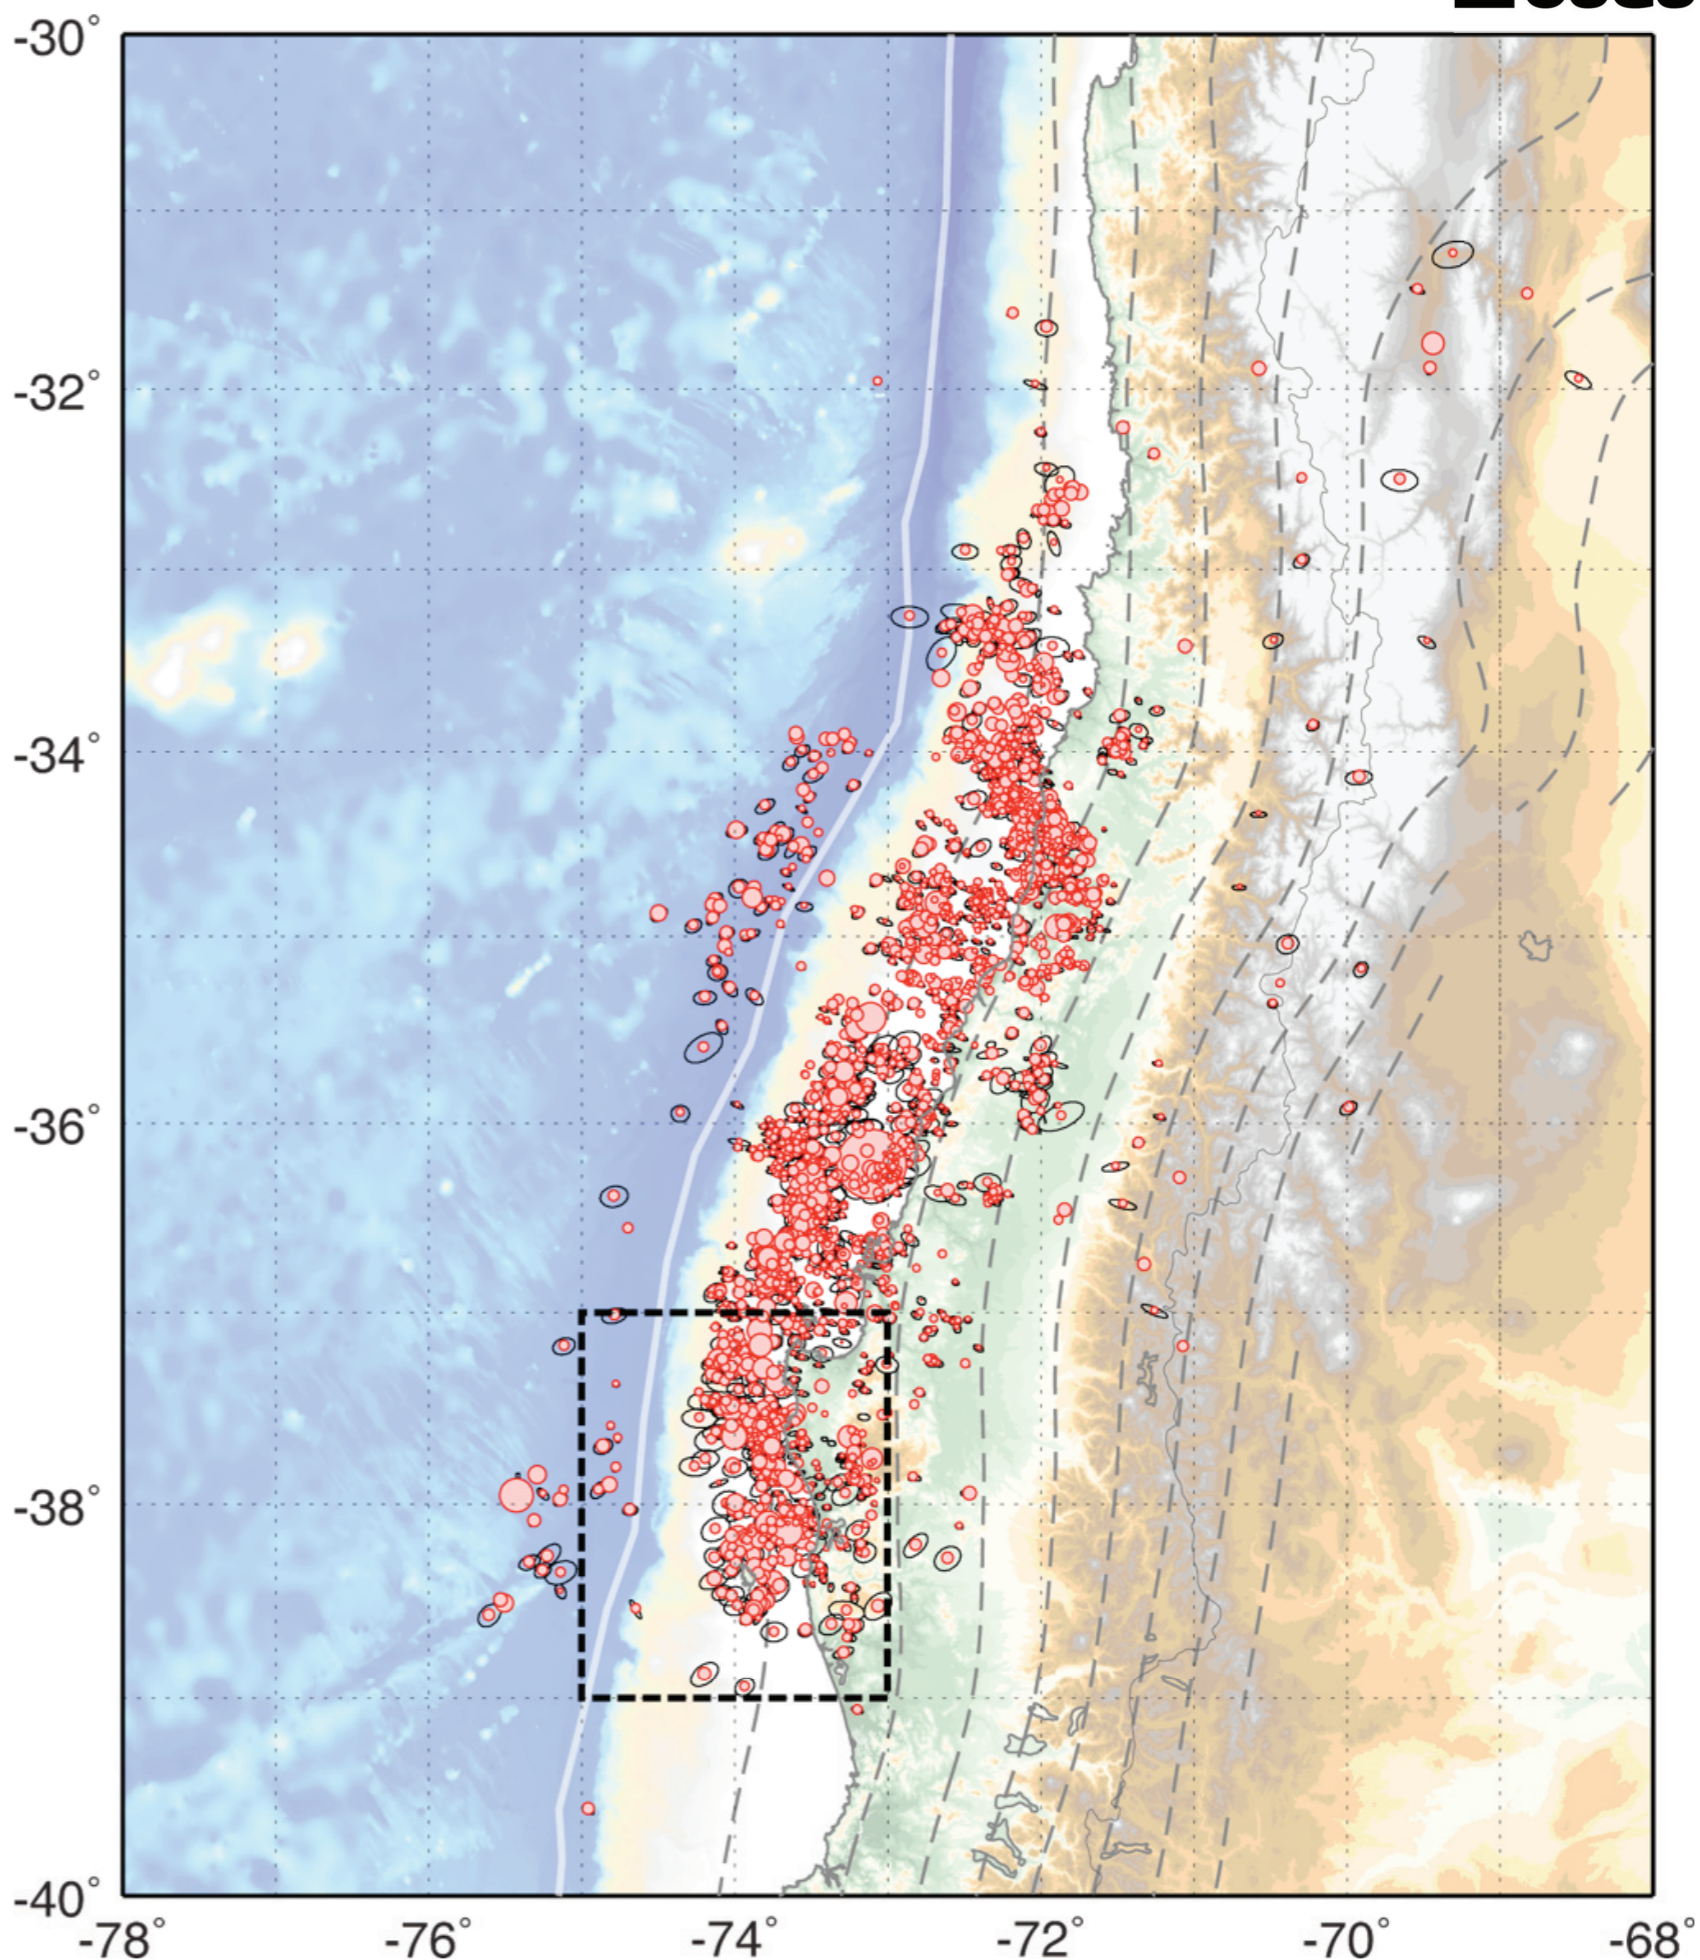

Vertical uncertainty averages $\pm 3-4$ km.

Relocated Aftershocks

Events relocated using both local/regional, and teleseismic phases (linkage provides higher accuracy for offshore events).

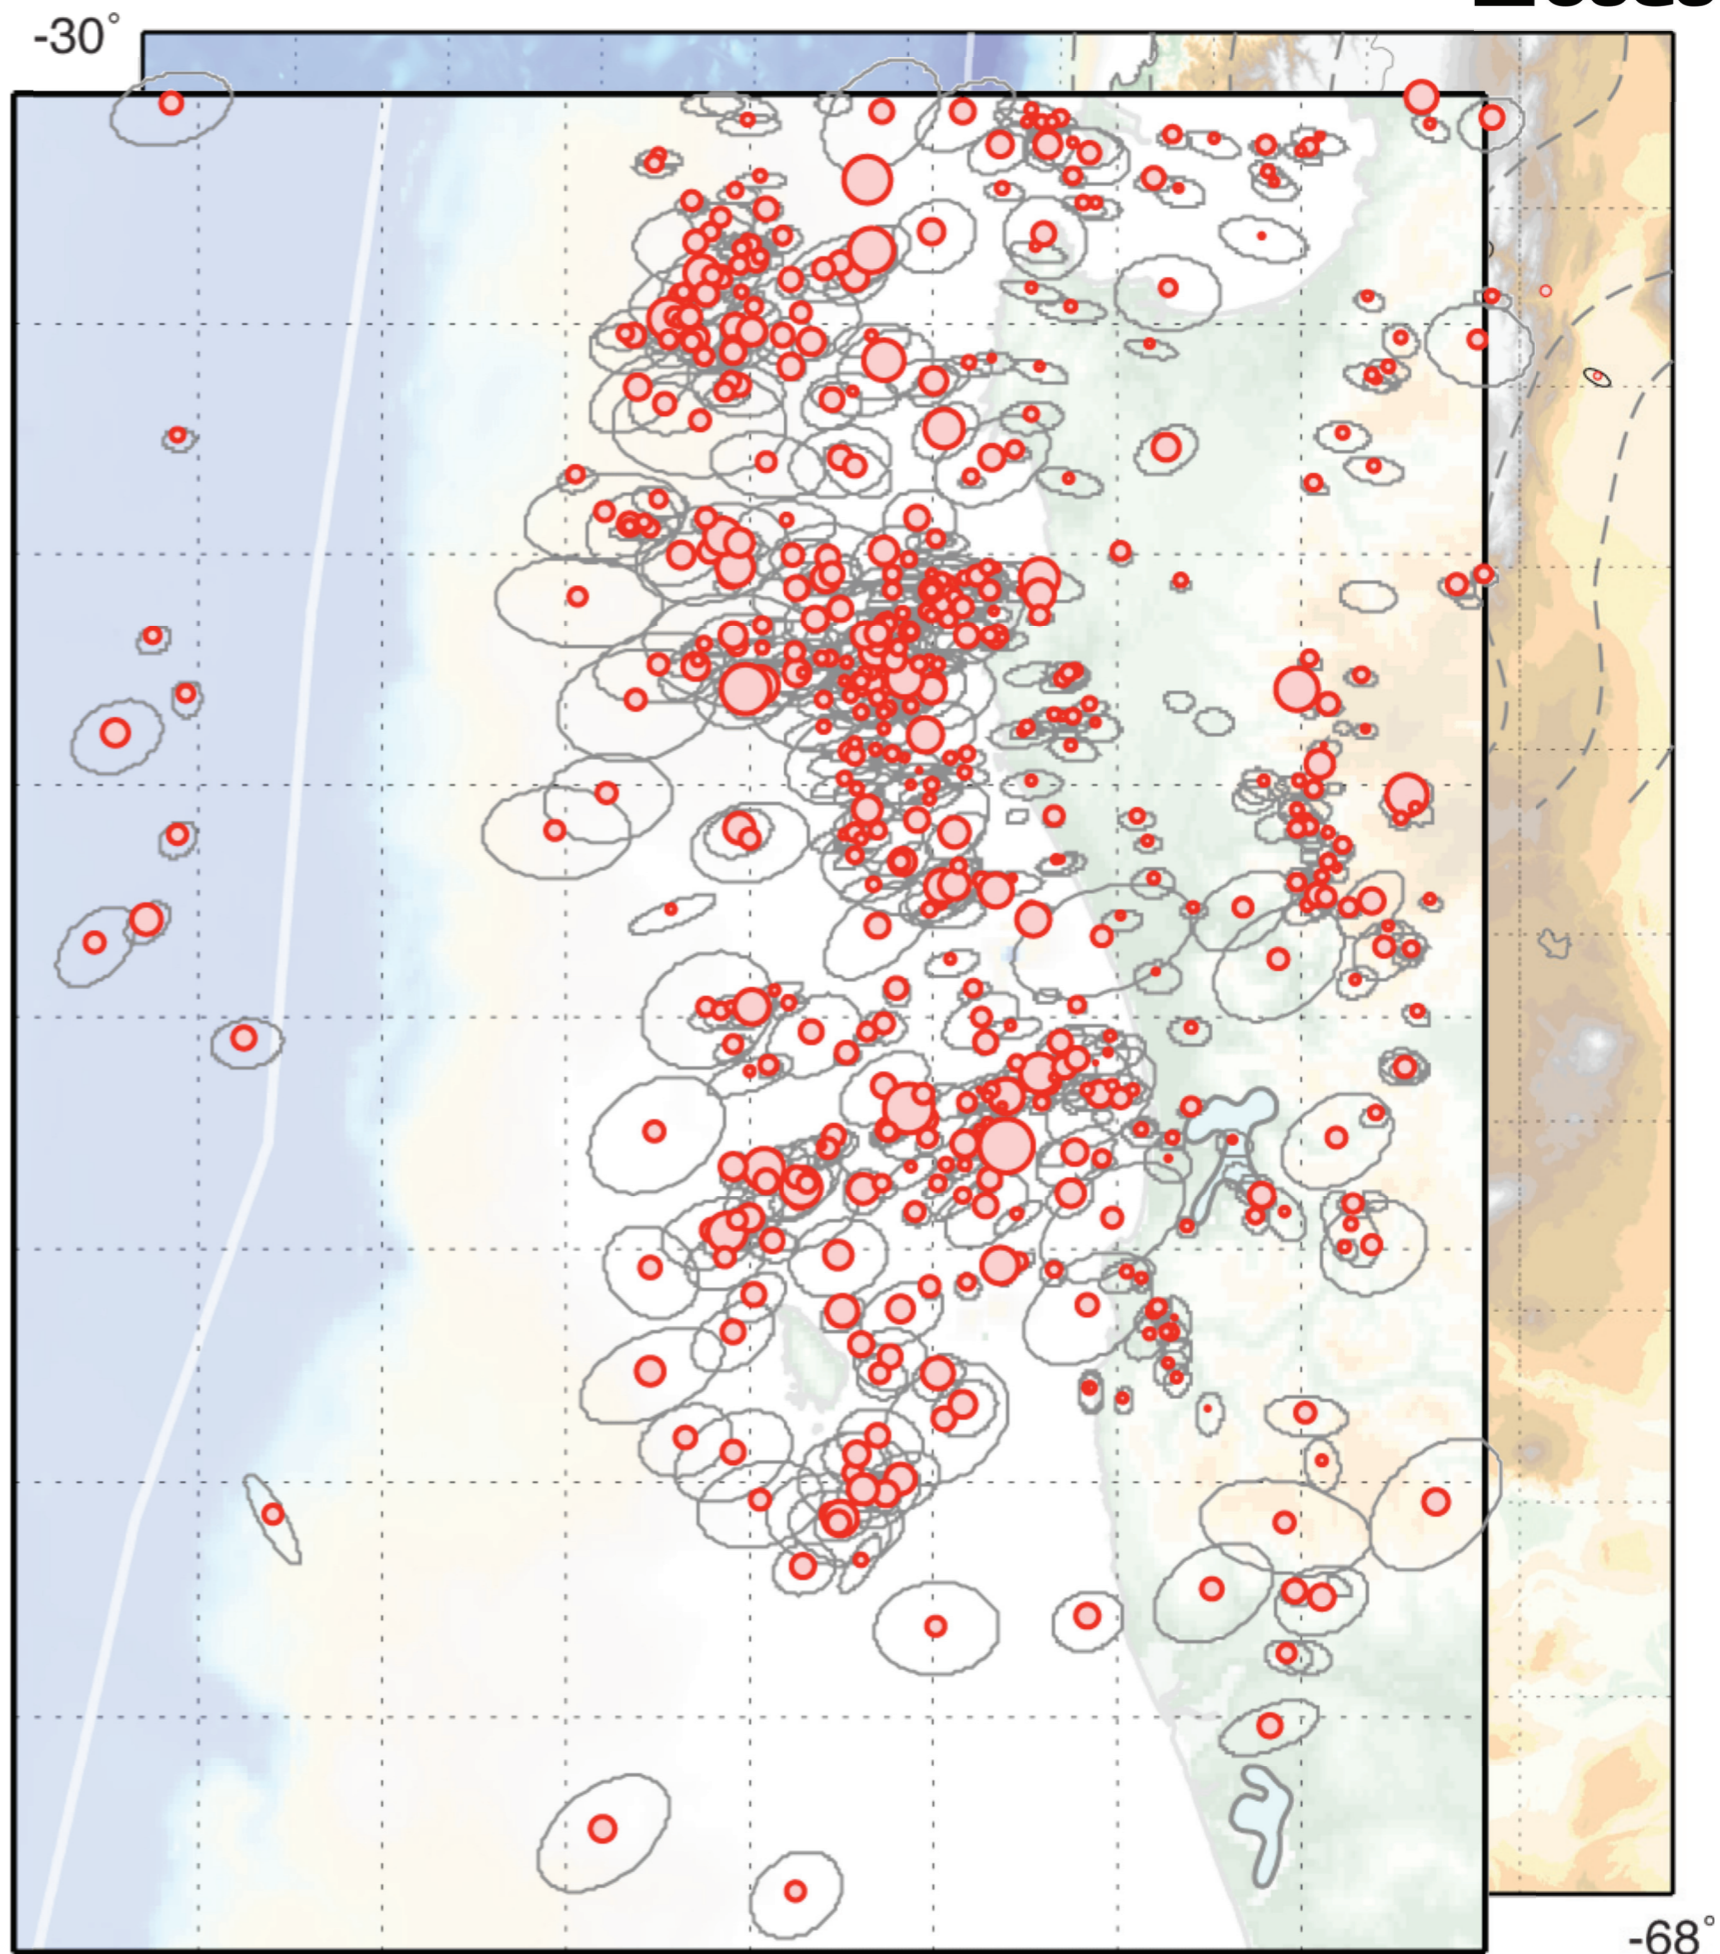

Uncertainties demonstrate dominant SW-NE/W-E orientation - i.e., bias in direction of network.

Relocated Aftershocks

Events relocated using both local/regional, and teleseismic phases (linkage provides higher accuracy for offshore events).

Uncertainties demonstrate dominant SW-NE/W-E orientation - i.e., bias in direction of network.

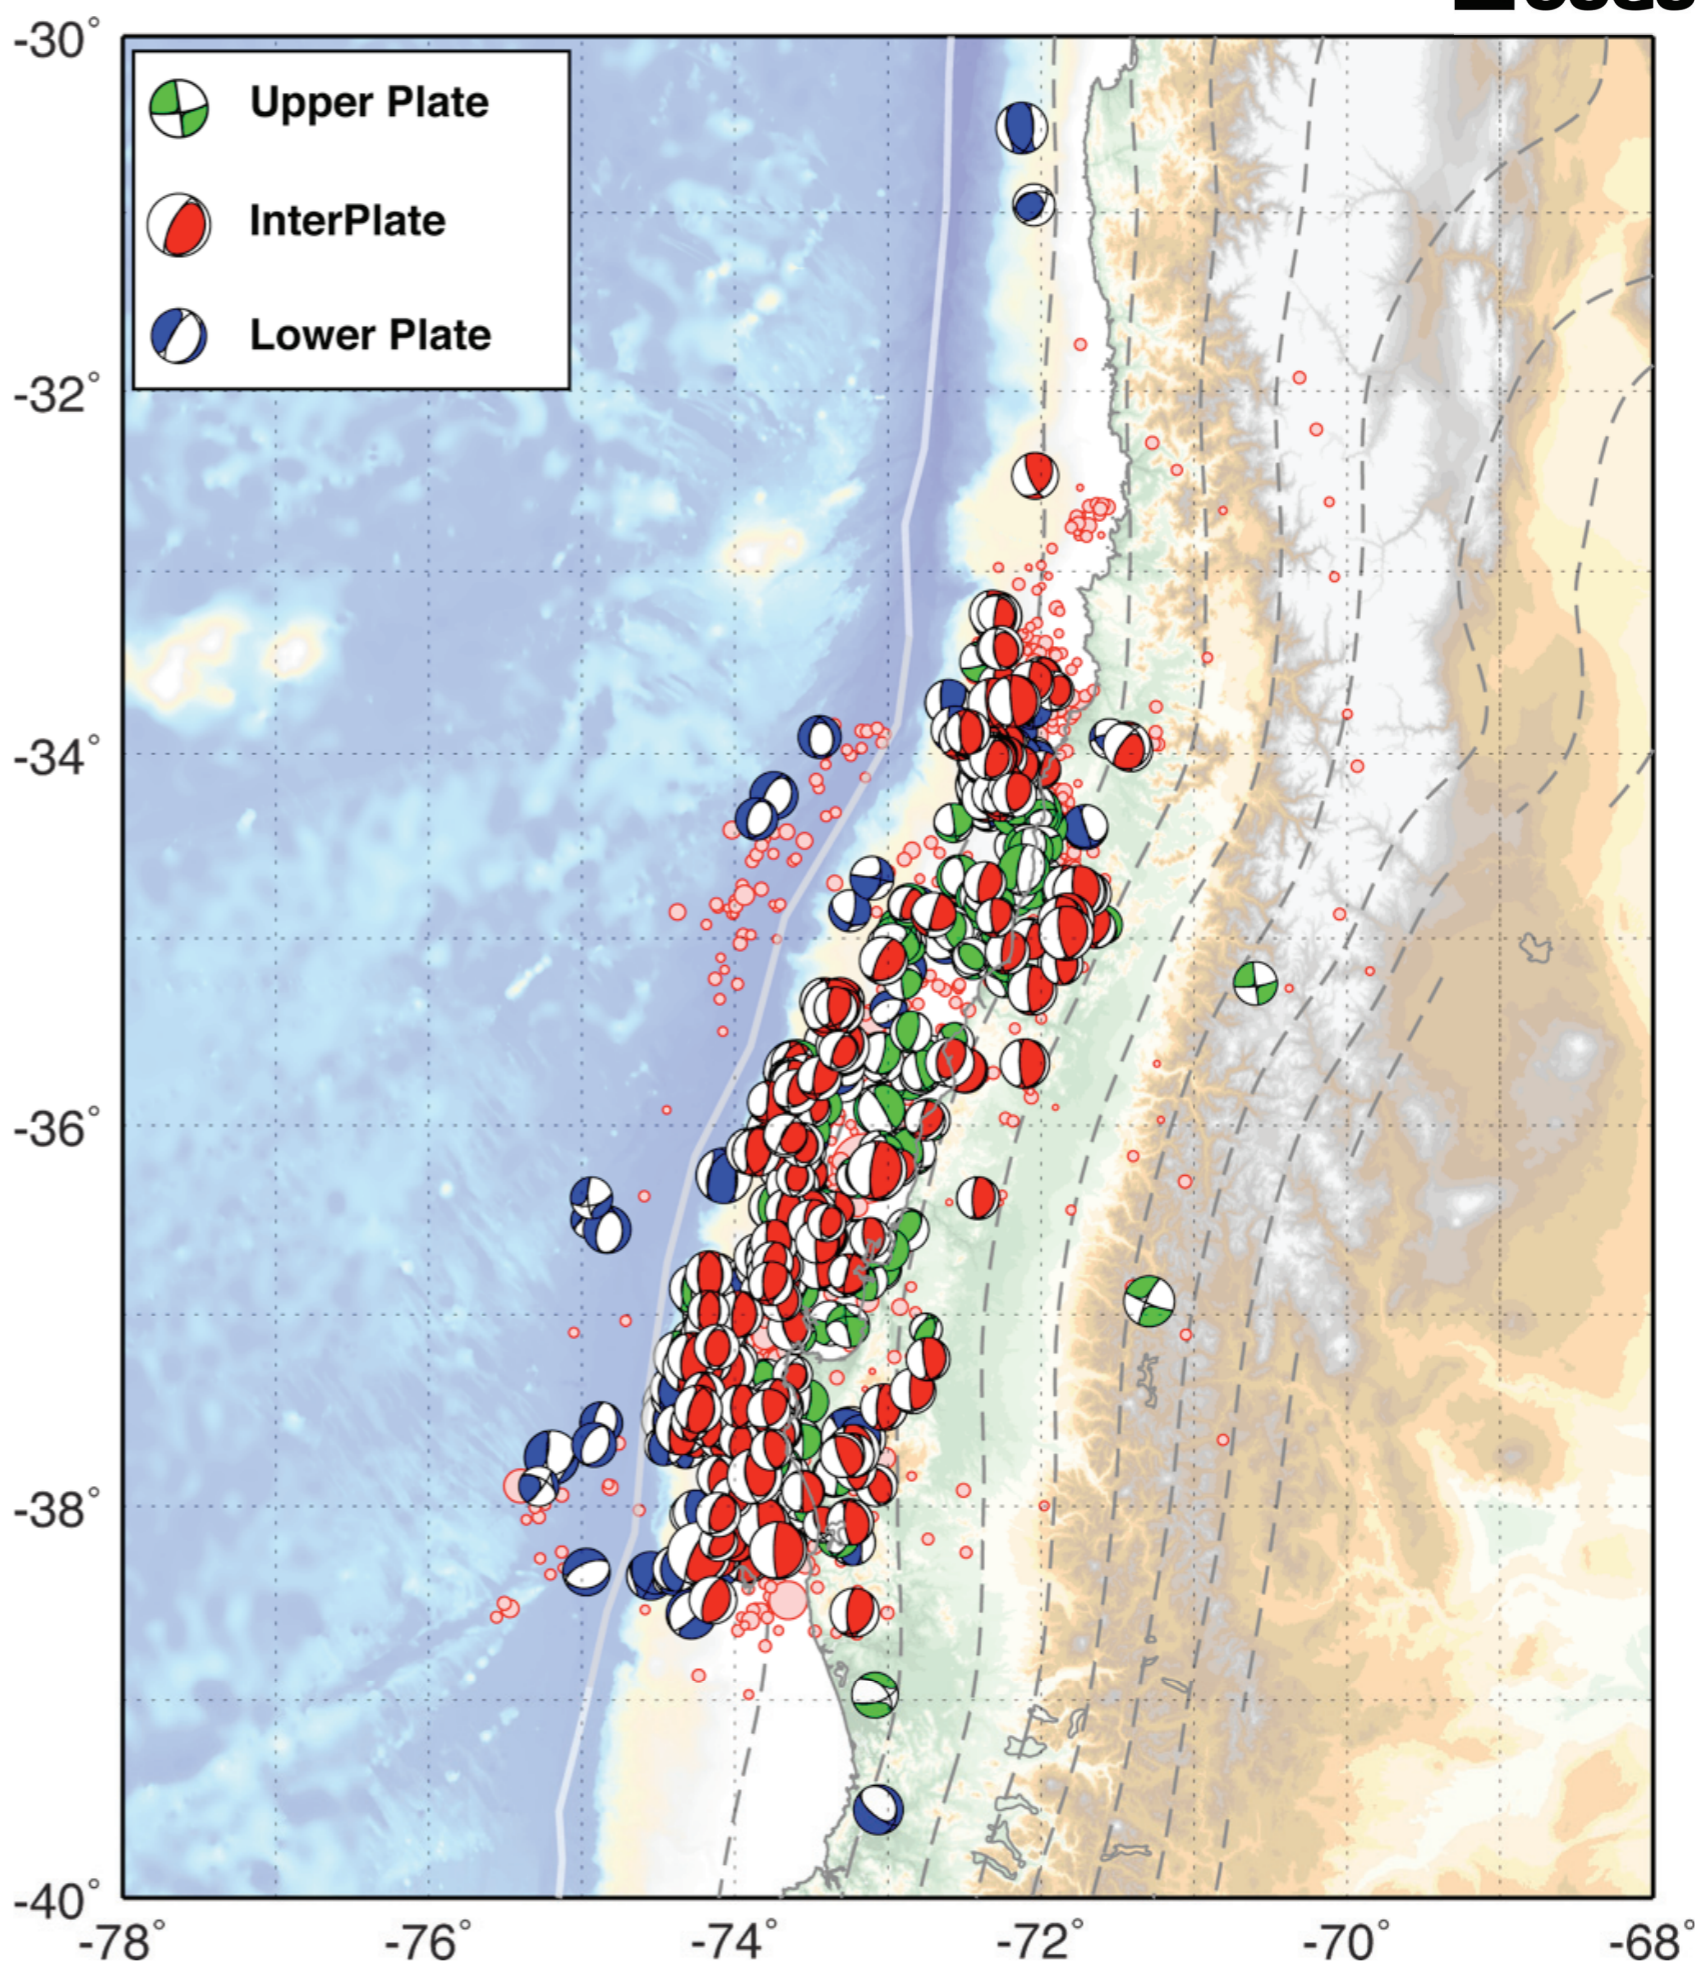

Maule RMTs

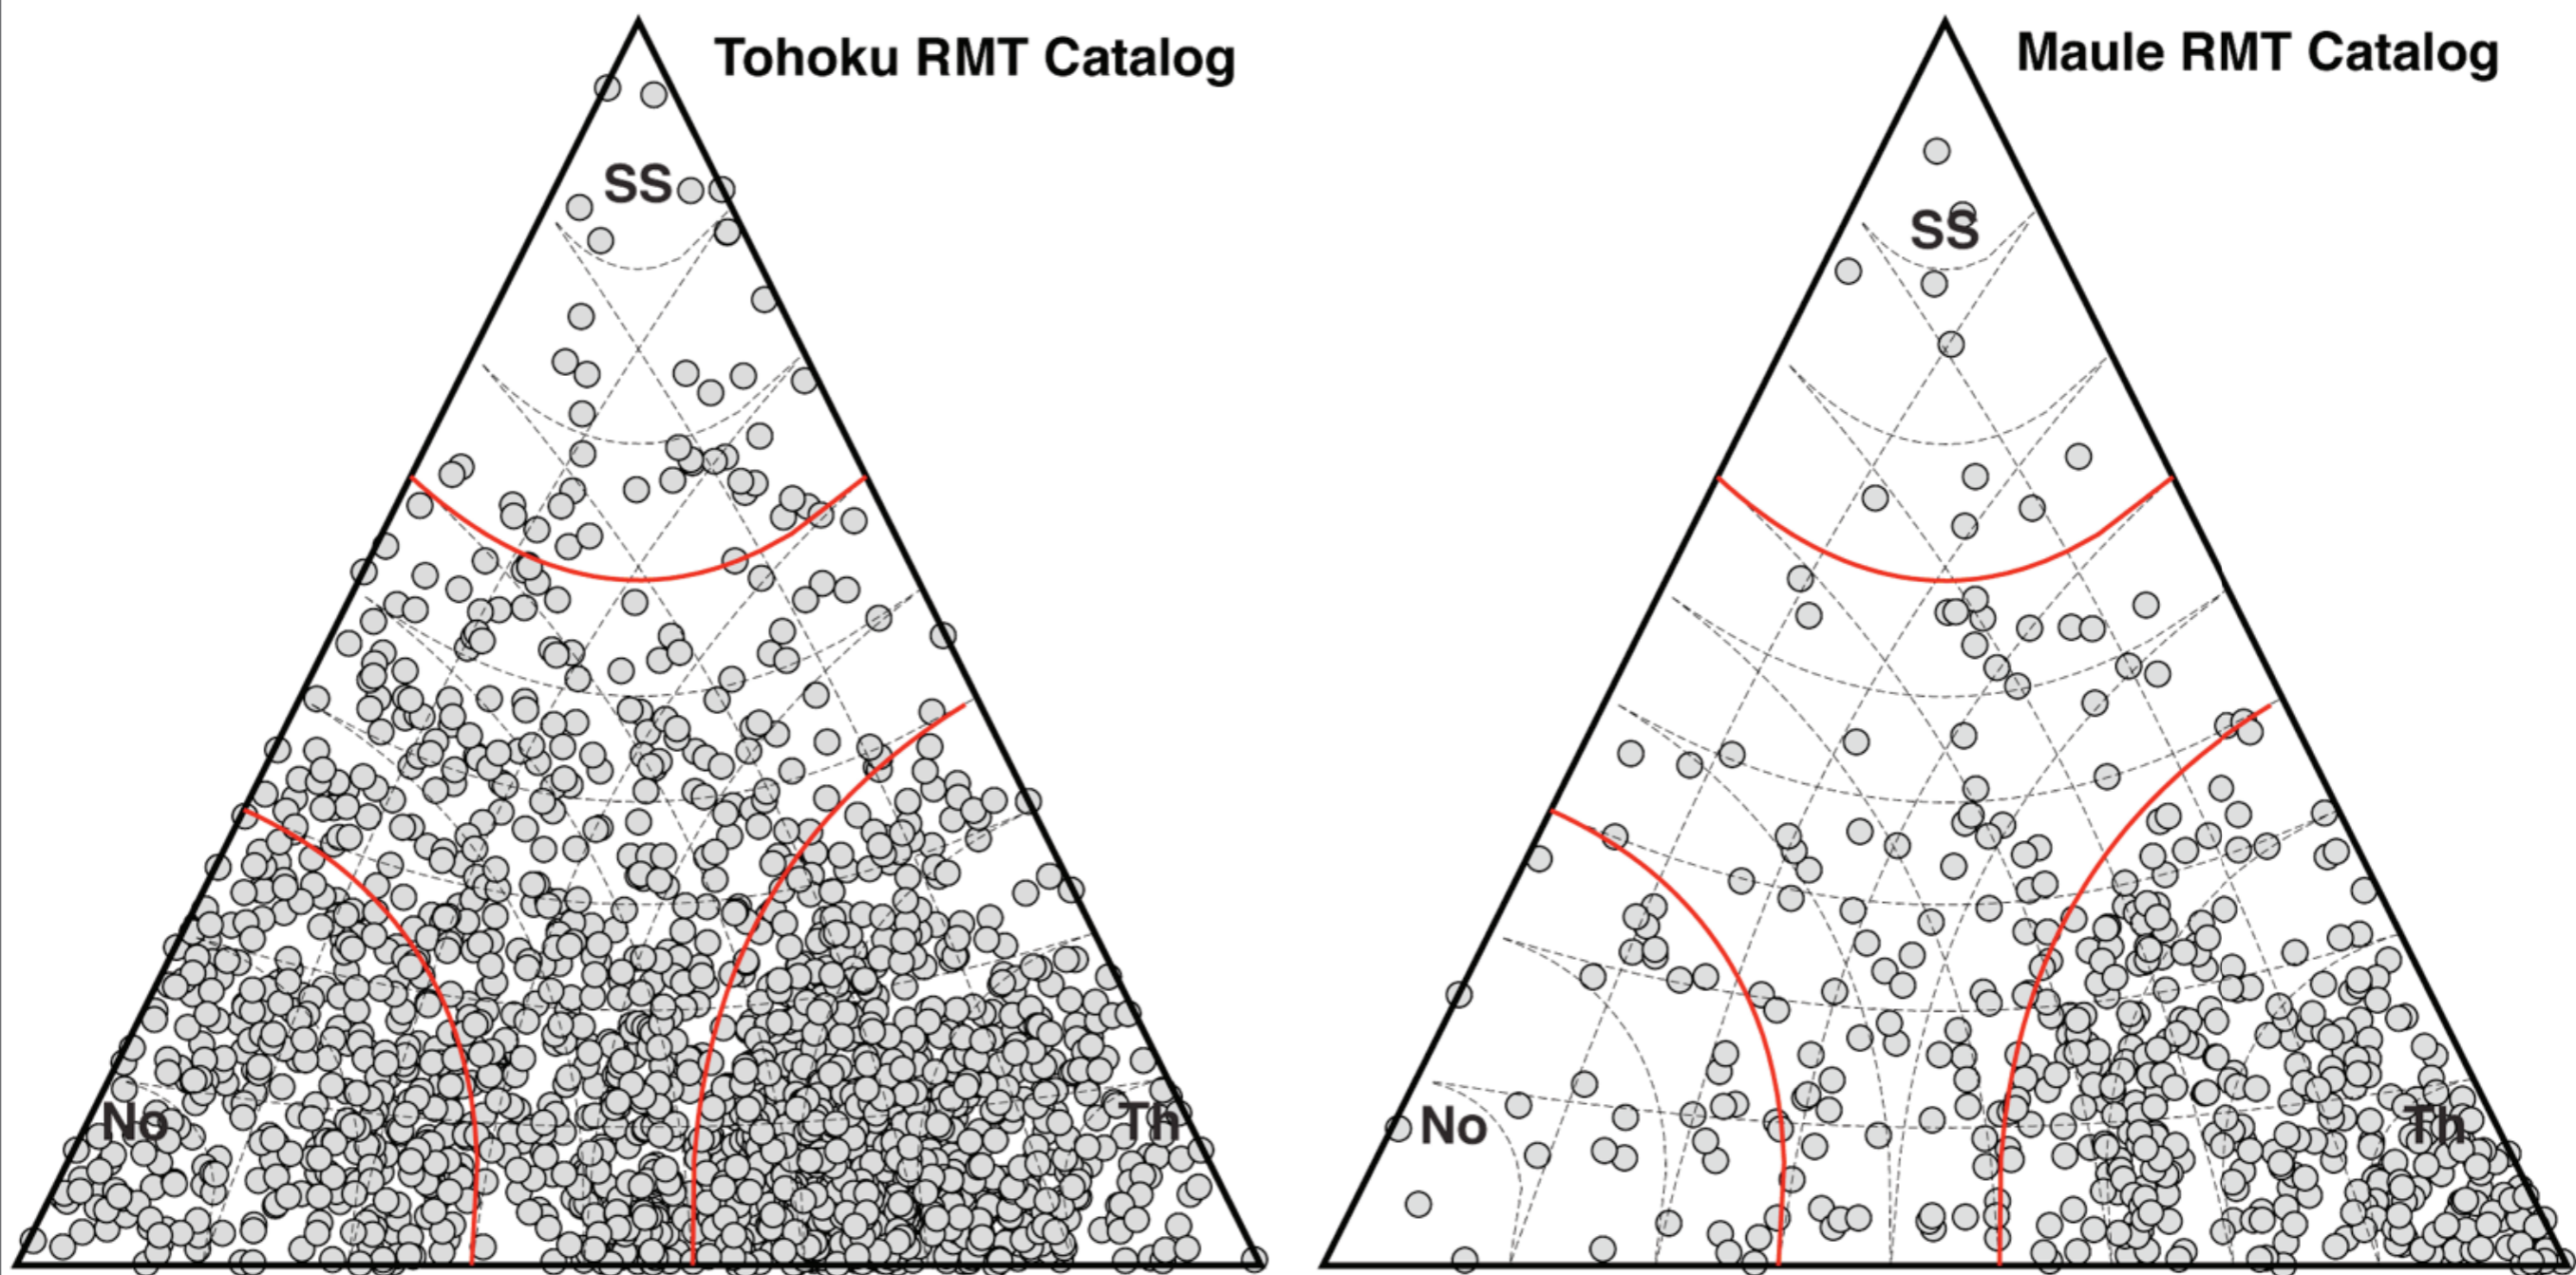

We have also used the PA Hydra system to produce regional moment tensors (RMT) for these earthquakes.

==> RMT catalog of 450 earthquakes, M3.5 and above.

Using these mechanisms and our slab models for the region, we can begin to analyze the tectonics of the sequence, dividing the catalog into upper, lower and interplate EQs.

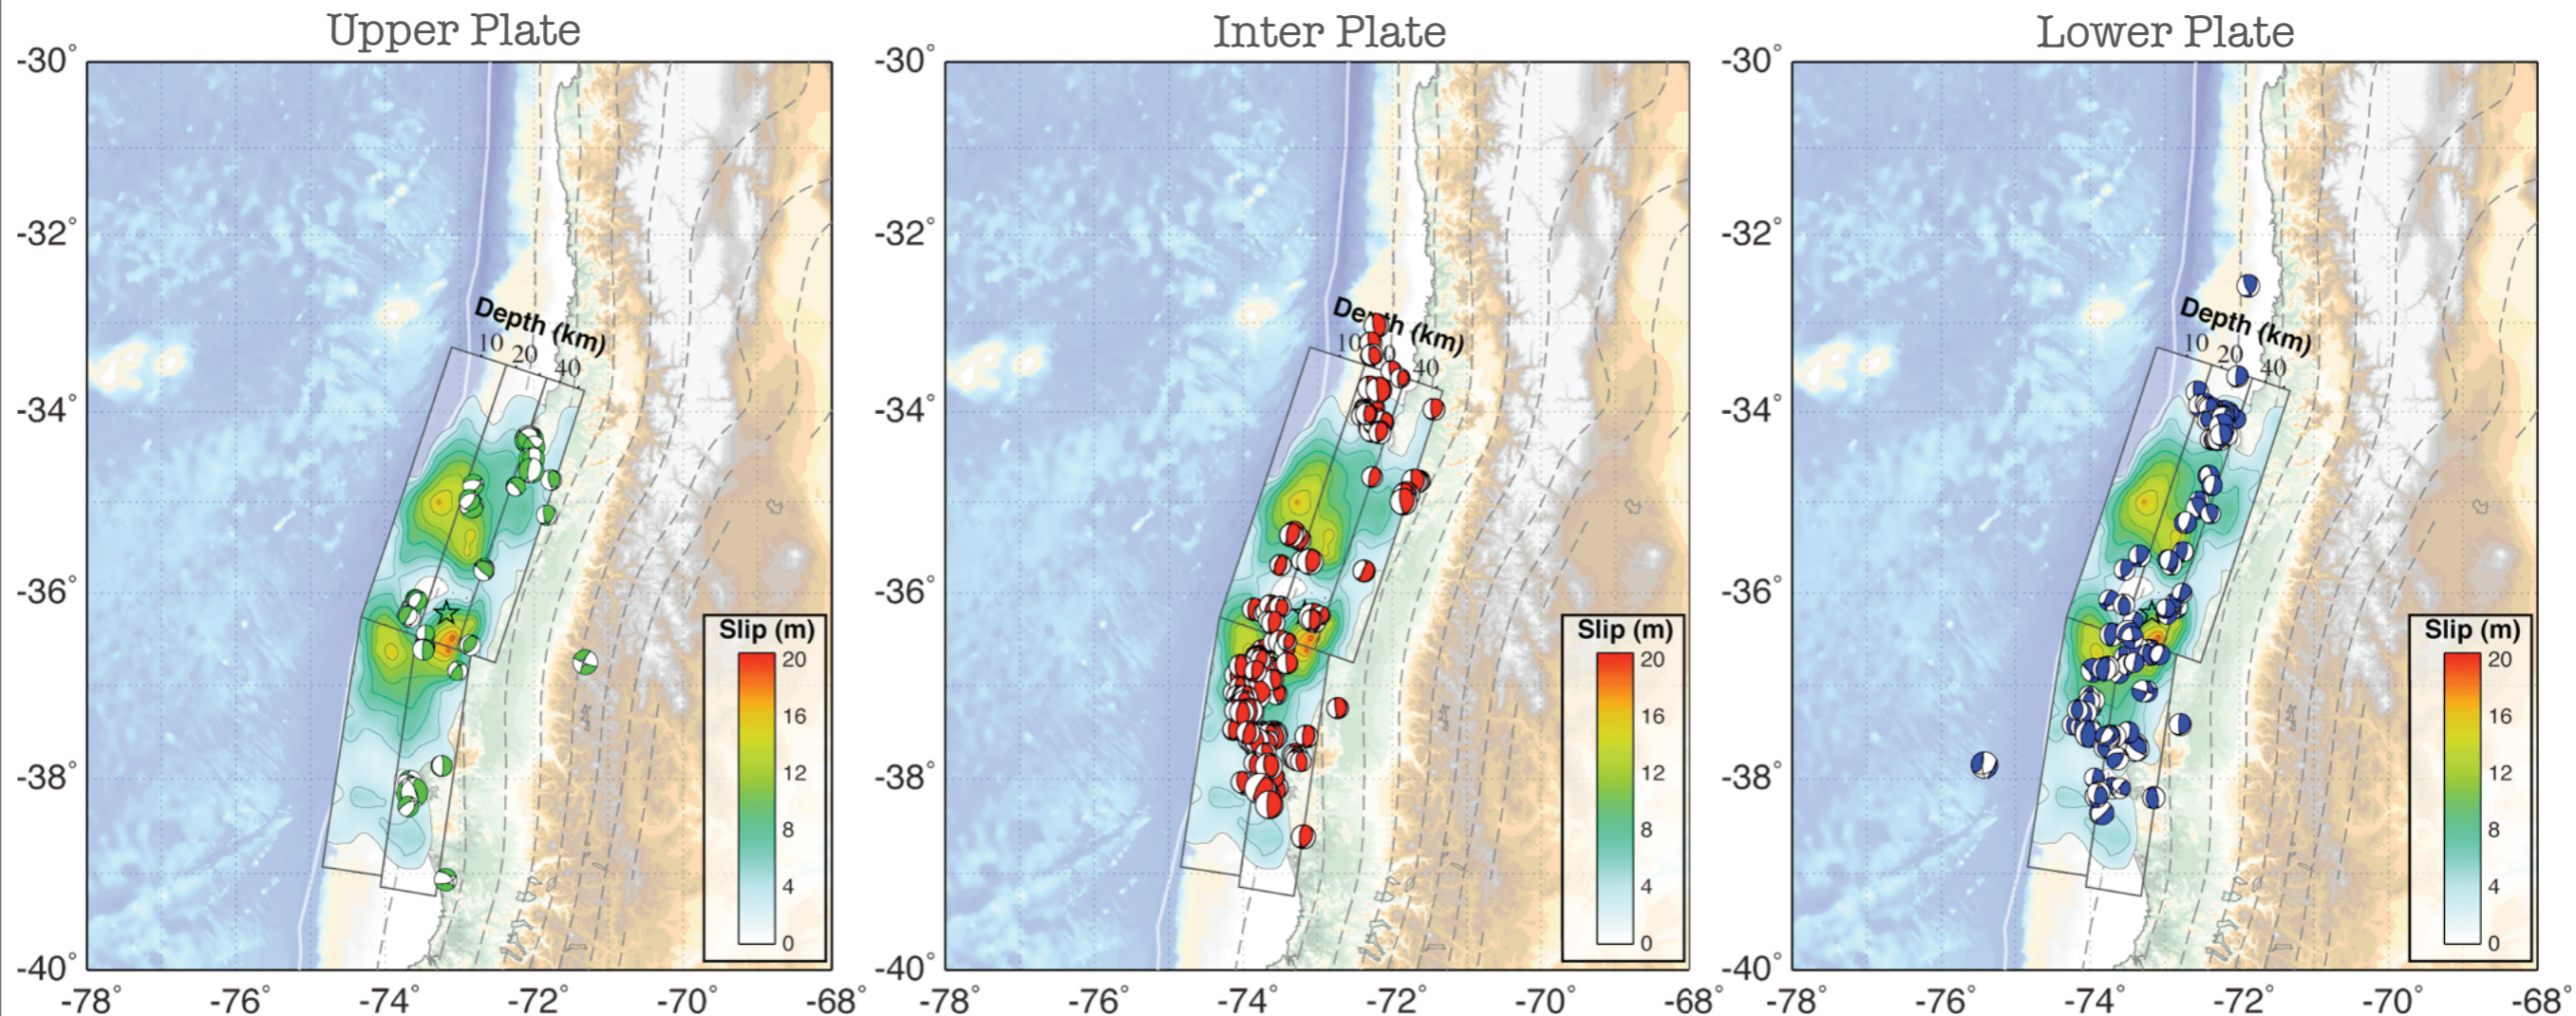

Maule RMTs

Maule moment tensors predominantly thrust, with some distributed normal and oblique faulting events.

Maule RMTs: Well-Constrained

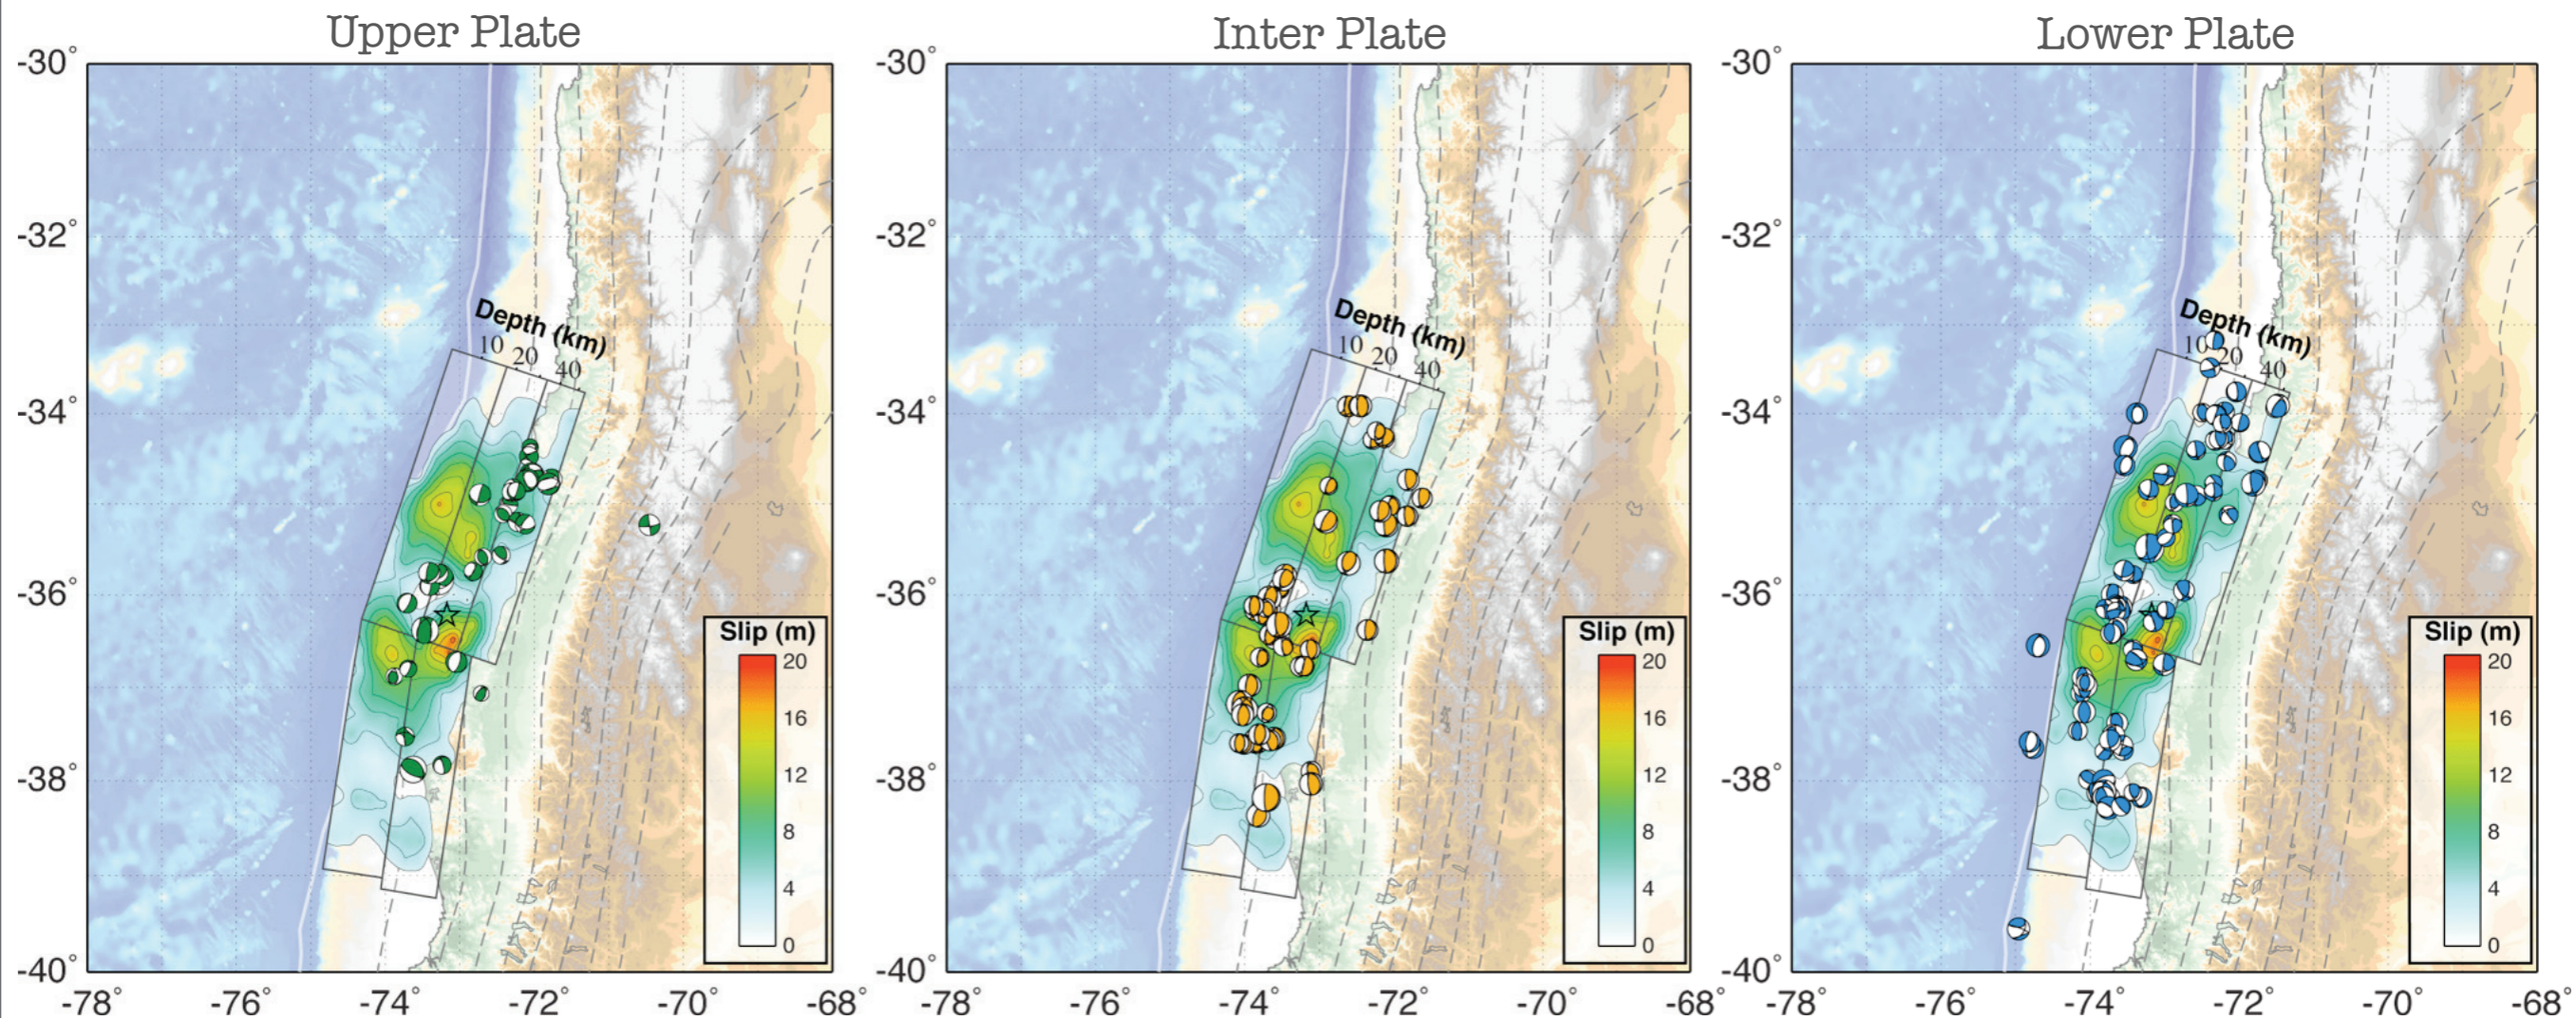

Majority of aftershocks interplate (~55-70%, depending on how data are filtered for tectonic regime).

Large cluster of normal faulting earthquakes in north, near Pichilemu (two M6.9-7.0 EQs on 2010/03/11).

Lower plate faulting on steep reverse structures in the offshore regions north & south of the mainshock slip.

Maule RMTs: Poorly-Constrained

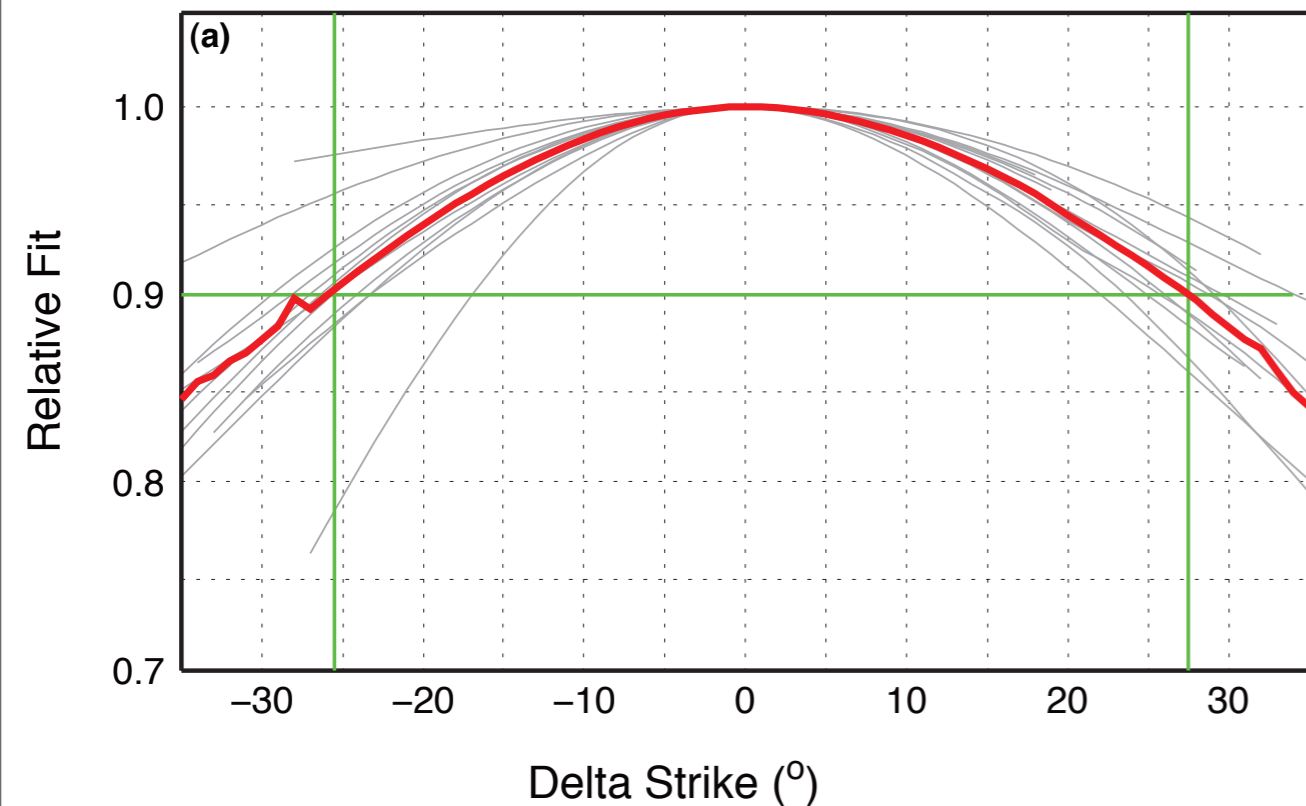

Majority of aftershocks interplate (~55-70%, depending on how data are filtered for tectonic regime).

Large cluster of normal faulting earthquakes in north, near Pichilemu (two M6.9-7.0 EQs on 2010/03/11).

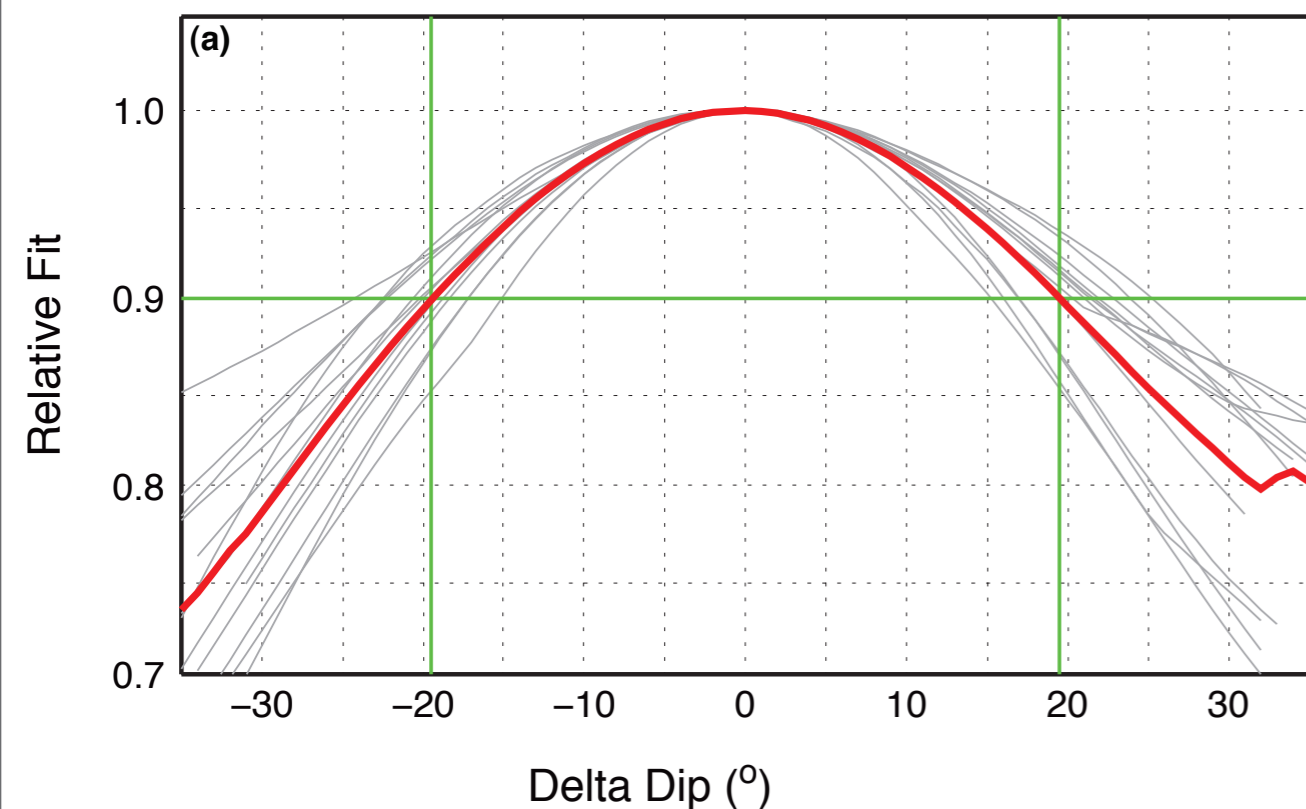

Lower plate faulting on steep reverse structures in the offshore regions north & south of the mainshock slip.

RMT Goodness of Fit Variations

Forward modeling fault plane solutions in Regional Moment Tensor inversions allows us to assess how well-constrained strike and dip are in RMT solutions.

‘Good’ solutions span +/- 25 deg in strike, +/- 20 deg in dip?

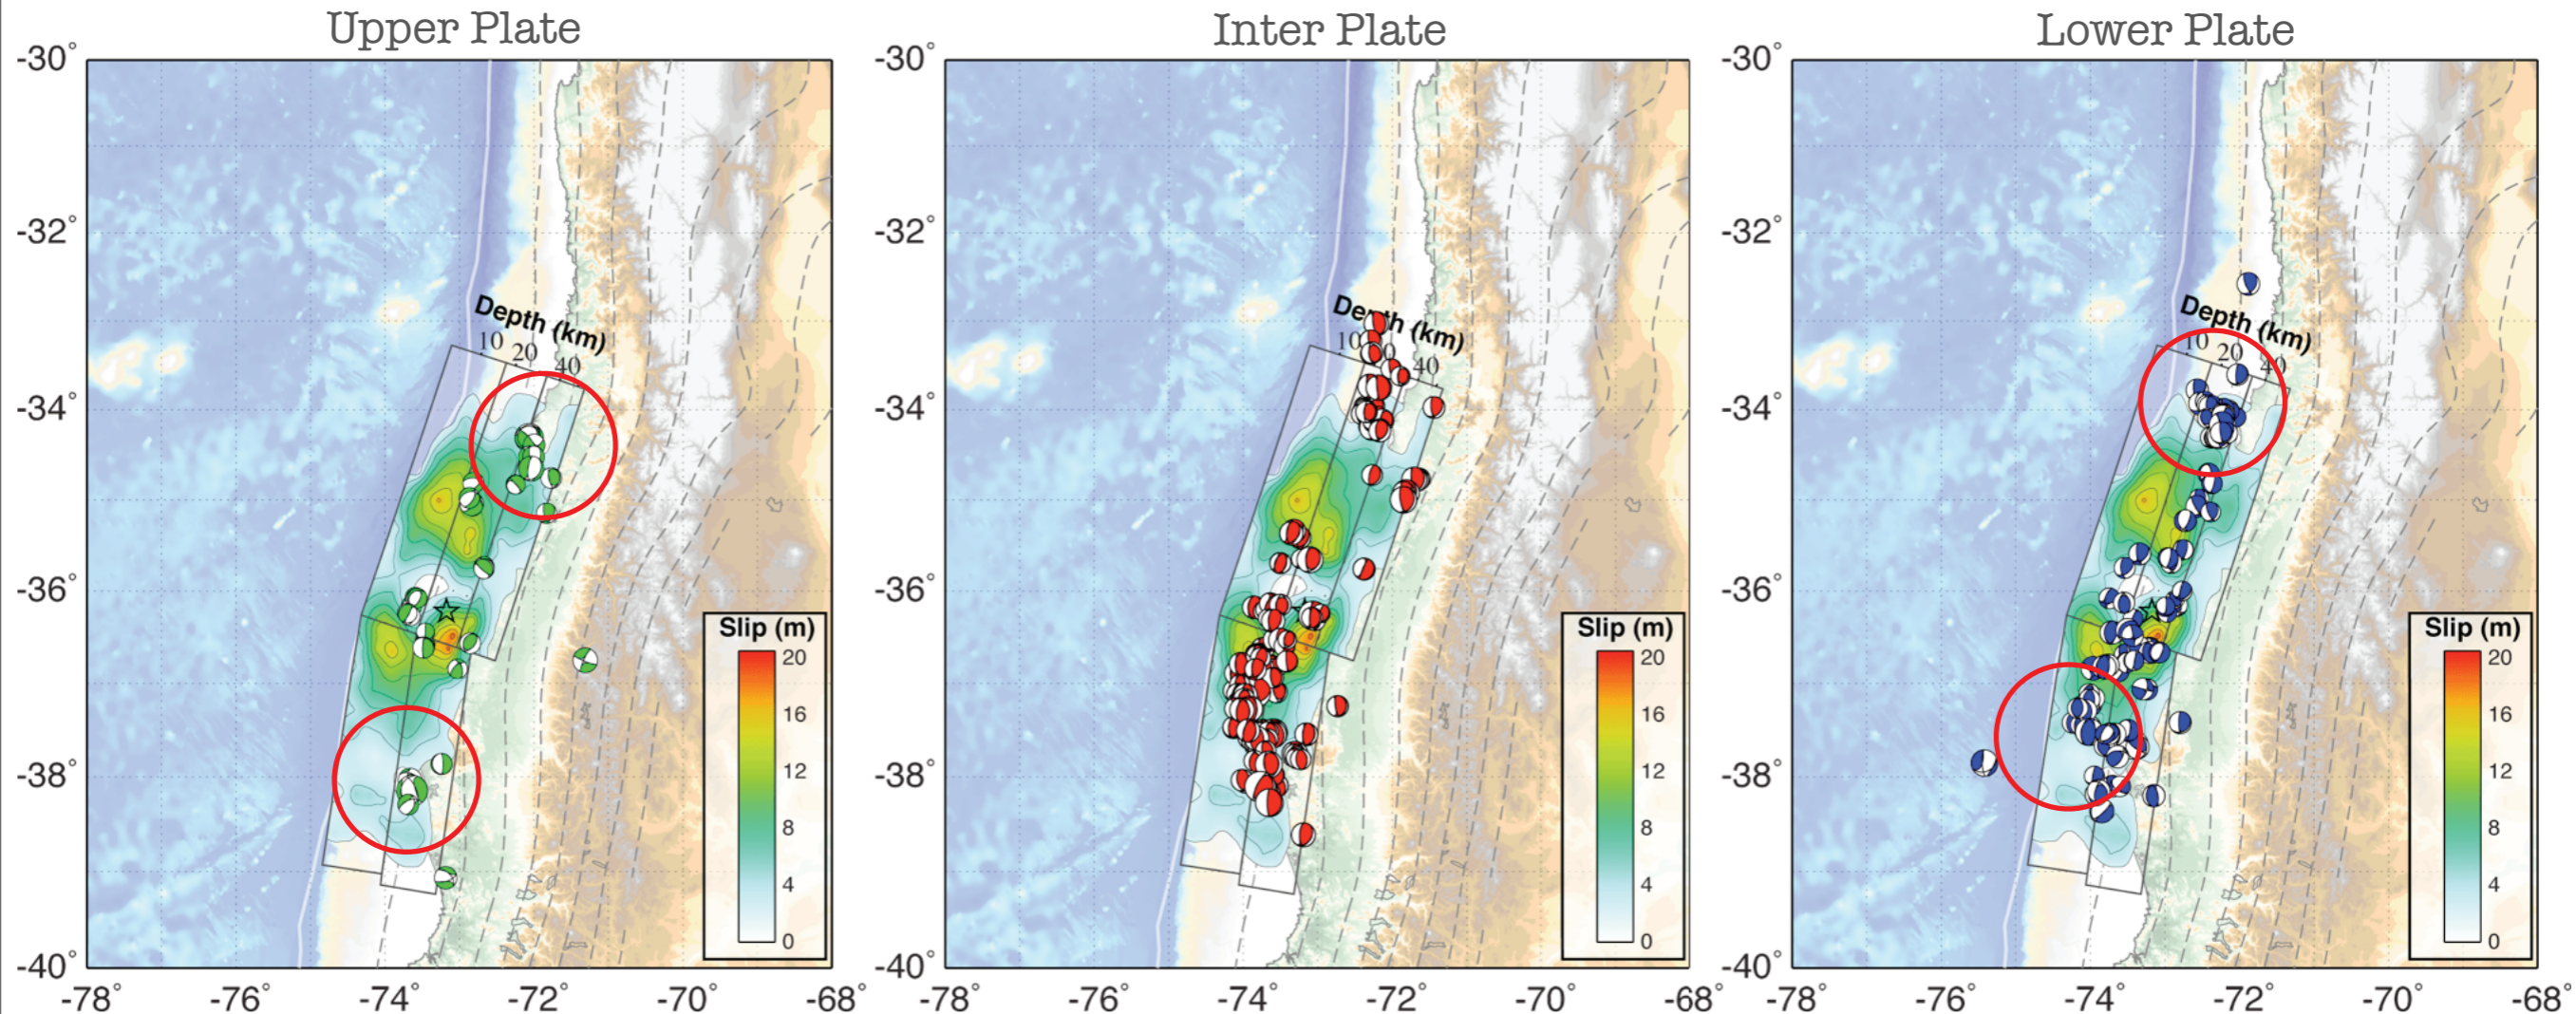

See **Kendra Johnson's** poster at this workshop.

RMT Uncertainty

Even when considering RMT uncertainties, thrust faulting solutions to the south & north of major coseismic slip are still confidently lower plate events.

Maule RMTs: Well-Constrained

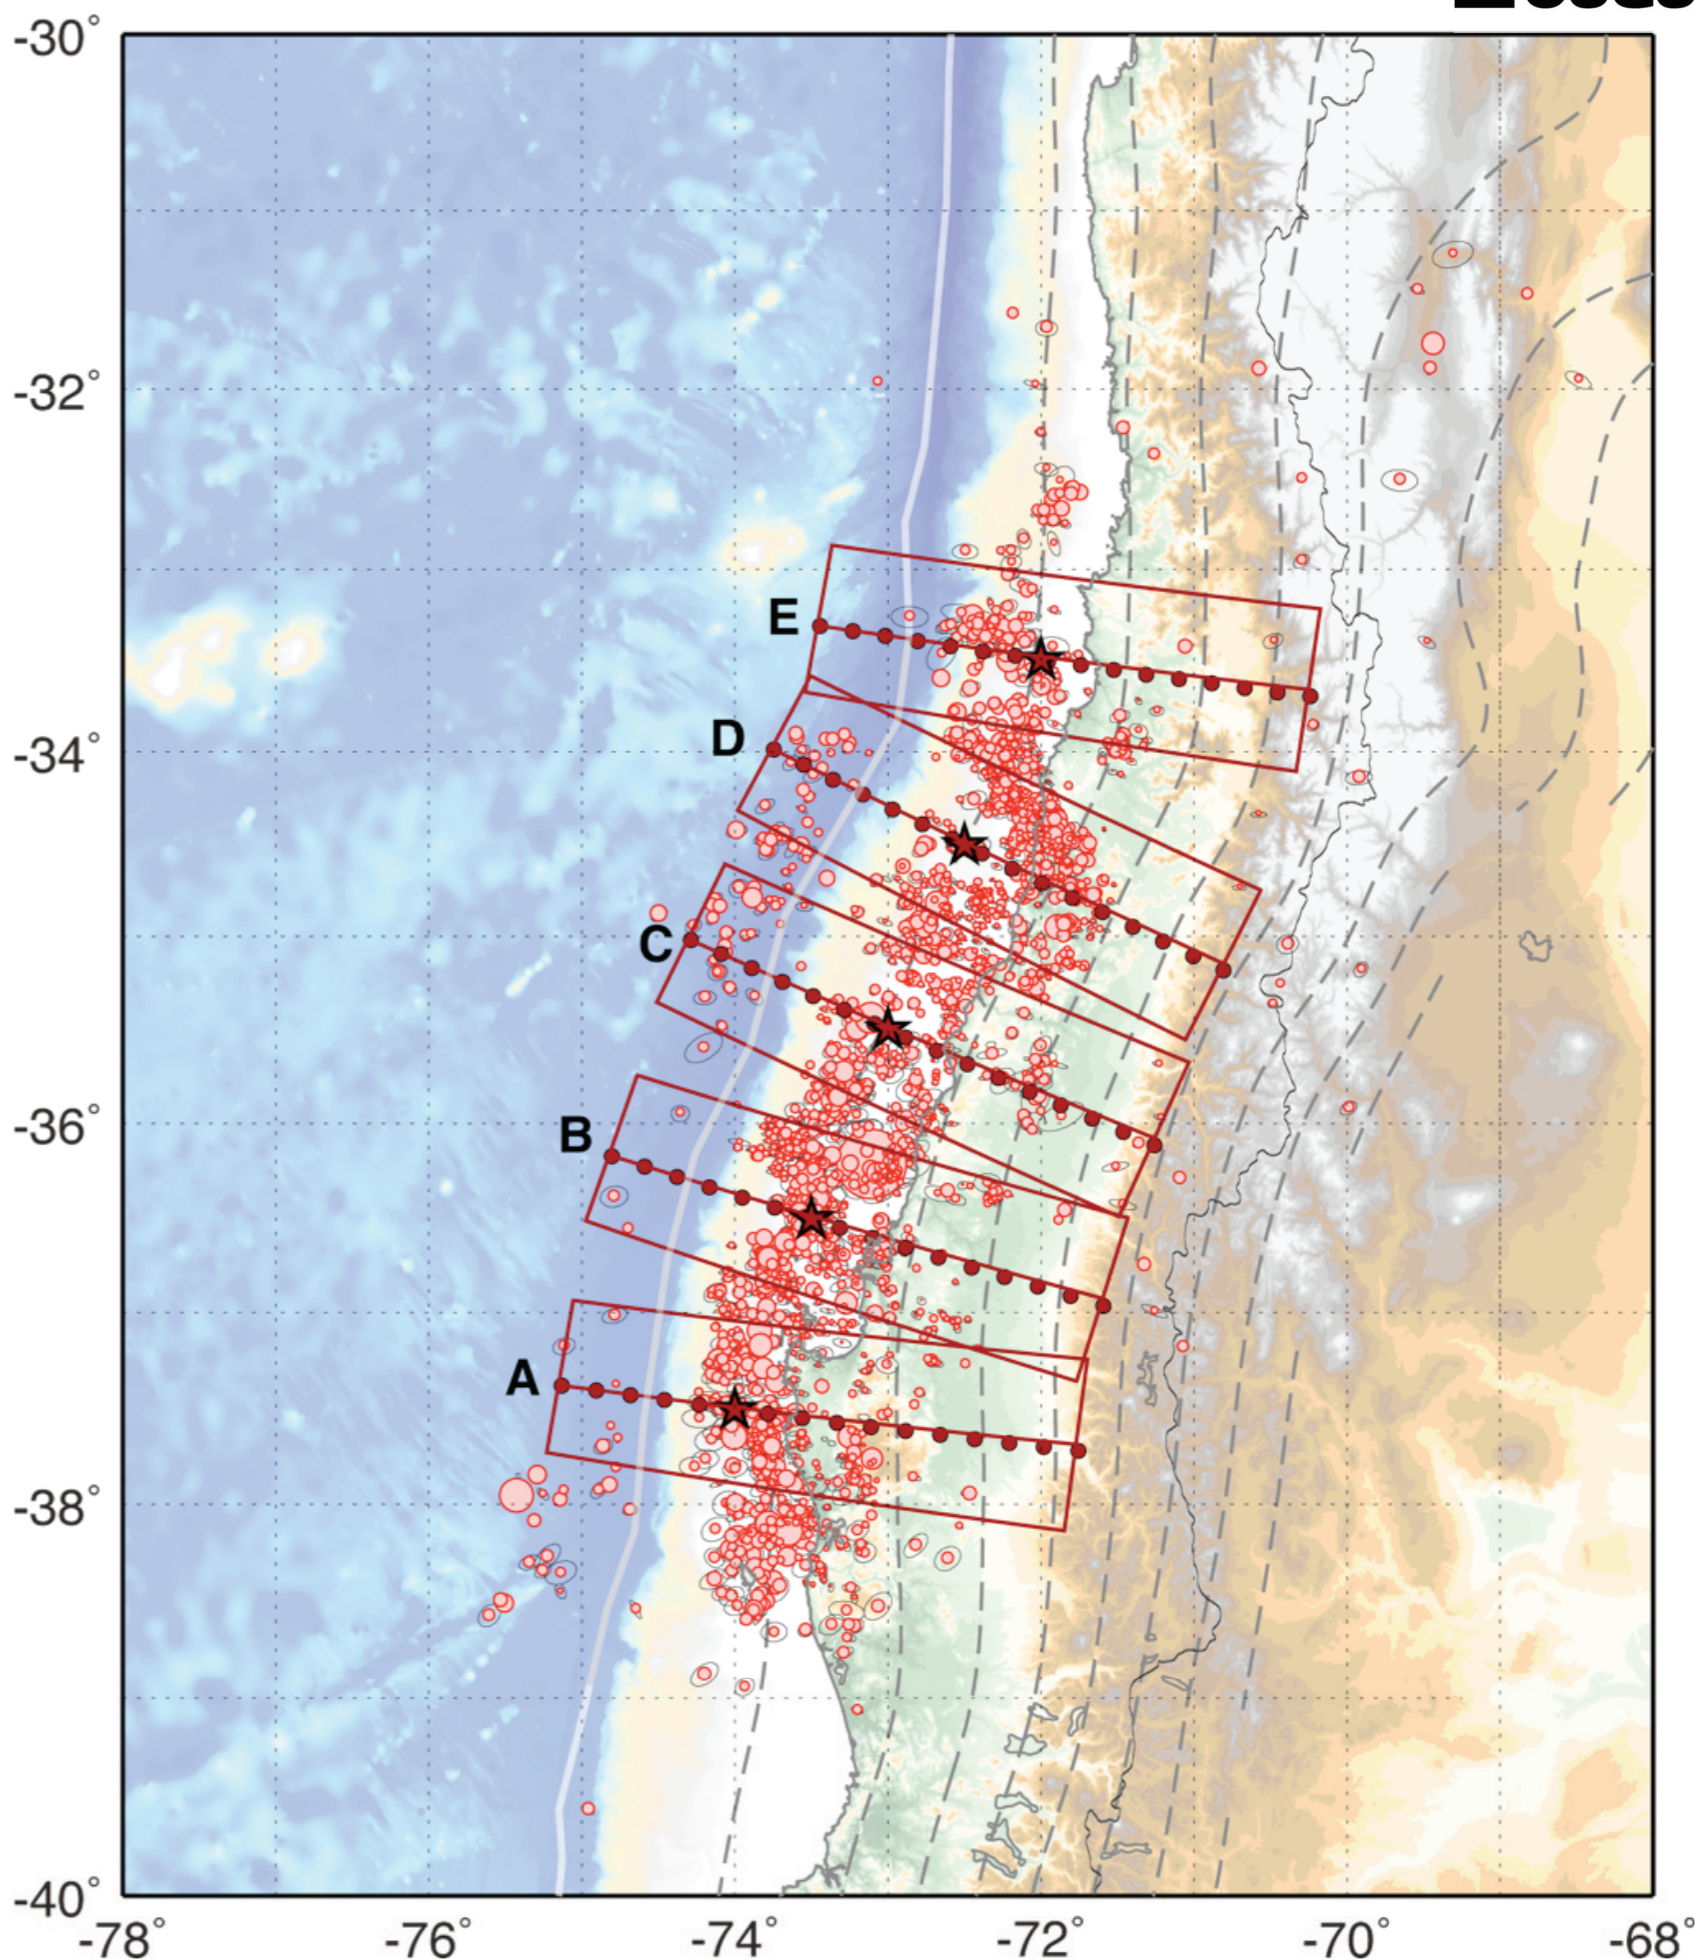

Even given the uncertainties of RMT solutions, these clusters of aftershocks near the limits of co-seismic slip cannot be interplate.

==> Upper and lower plates respond to co-seismic slip at ends of rupture.

Relocated Aftershocks

Cross-sections show structure of aftershock sequence with depth. Four dominant regions of activity:

- 1) Two clusters along interplate thrust (shallow & deep)
- 2) Upper plate, near Pichilemu
- 3) Outboard of SZ

Cross-Sections

Cross-Sections

Cross-Sections

Cross-Sections

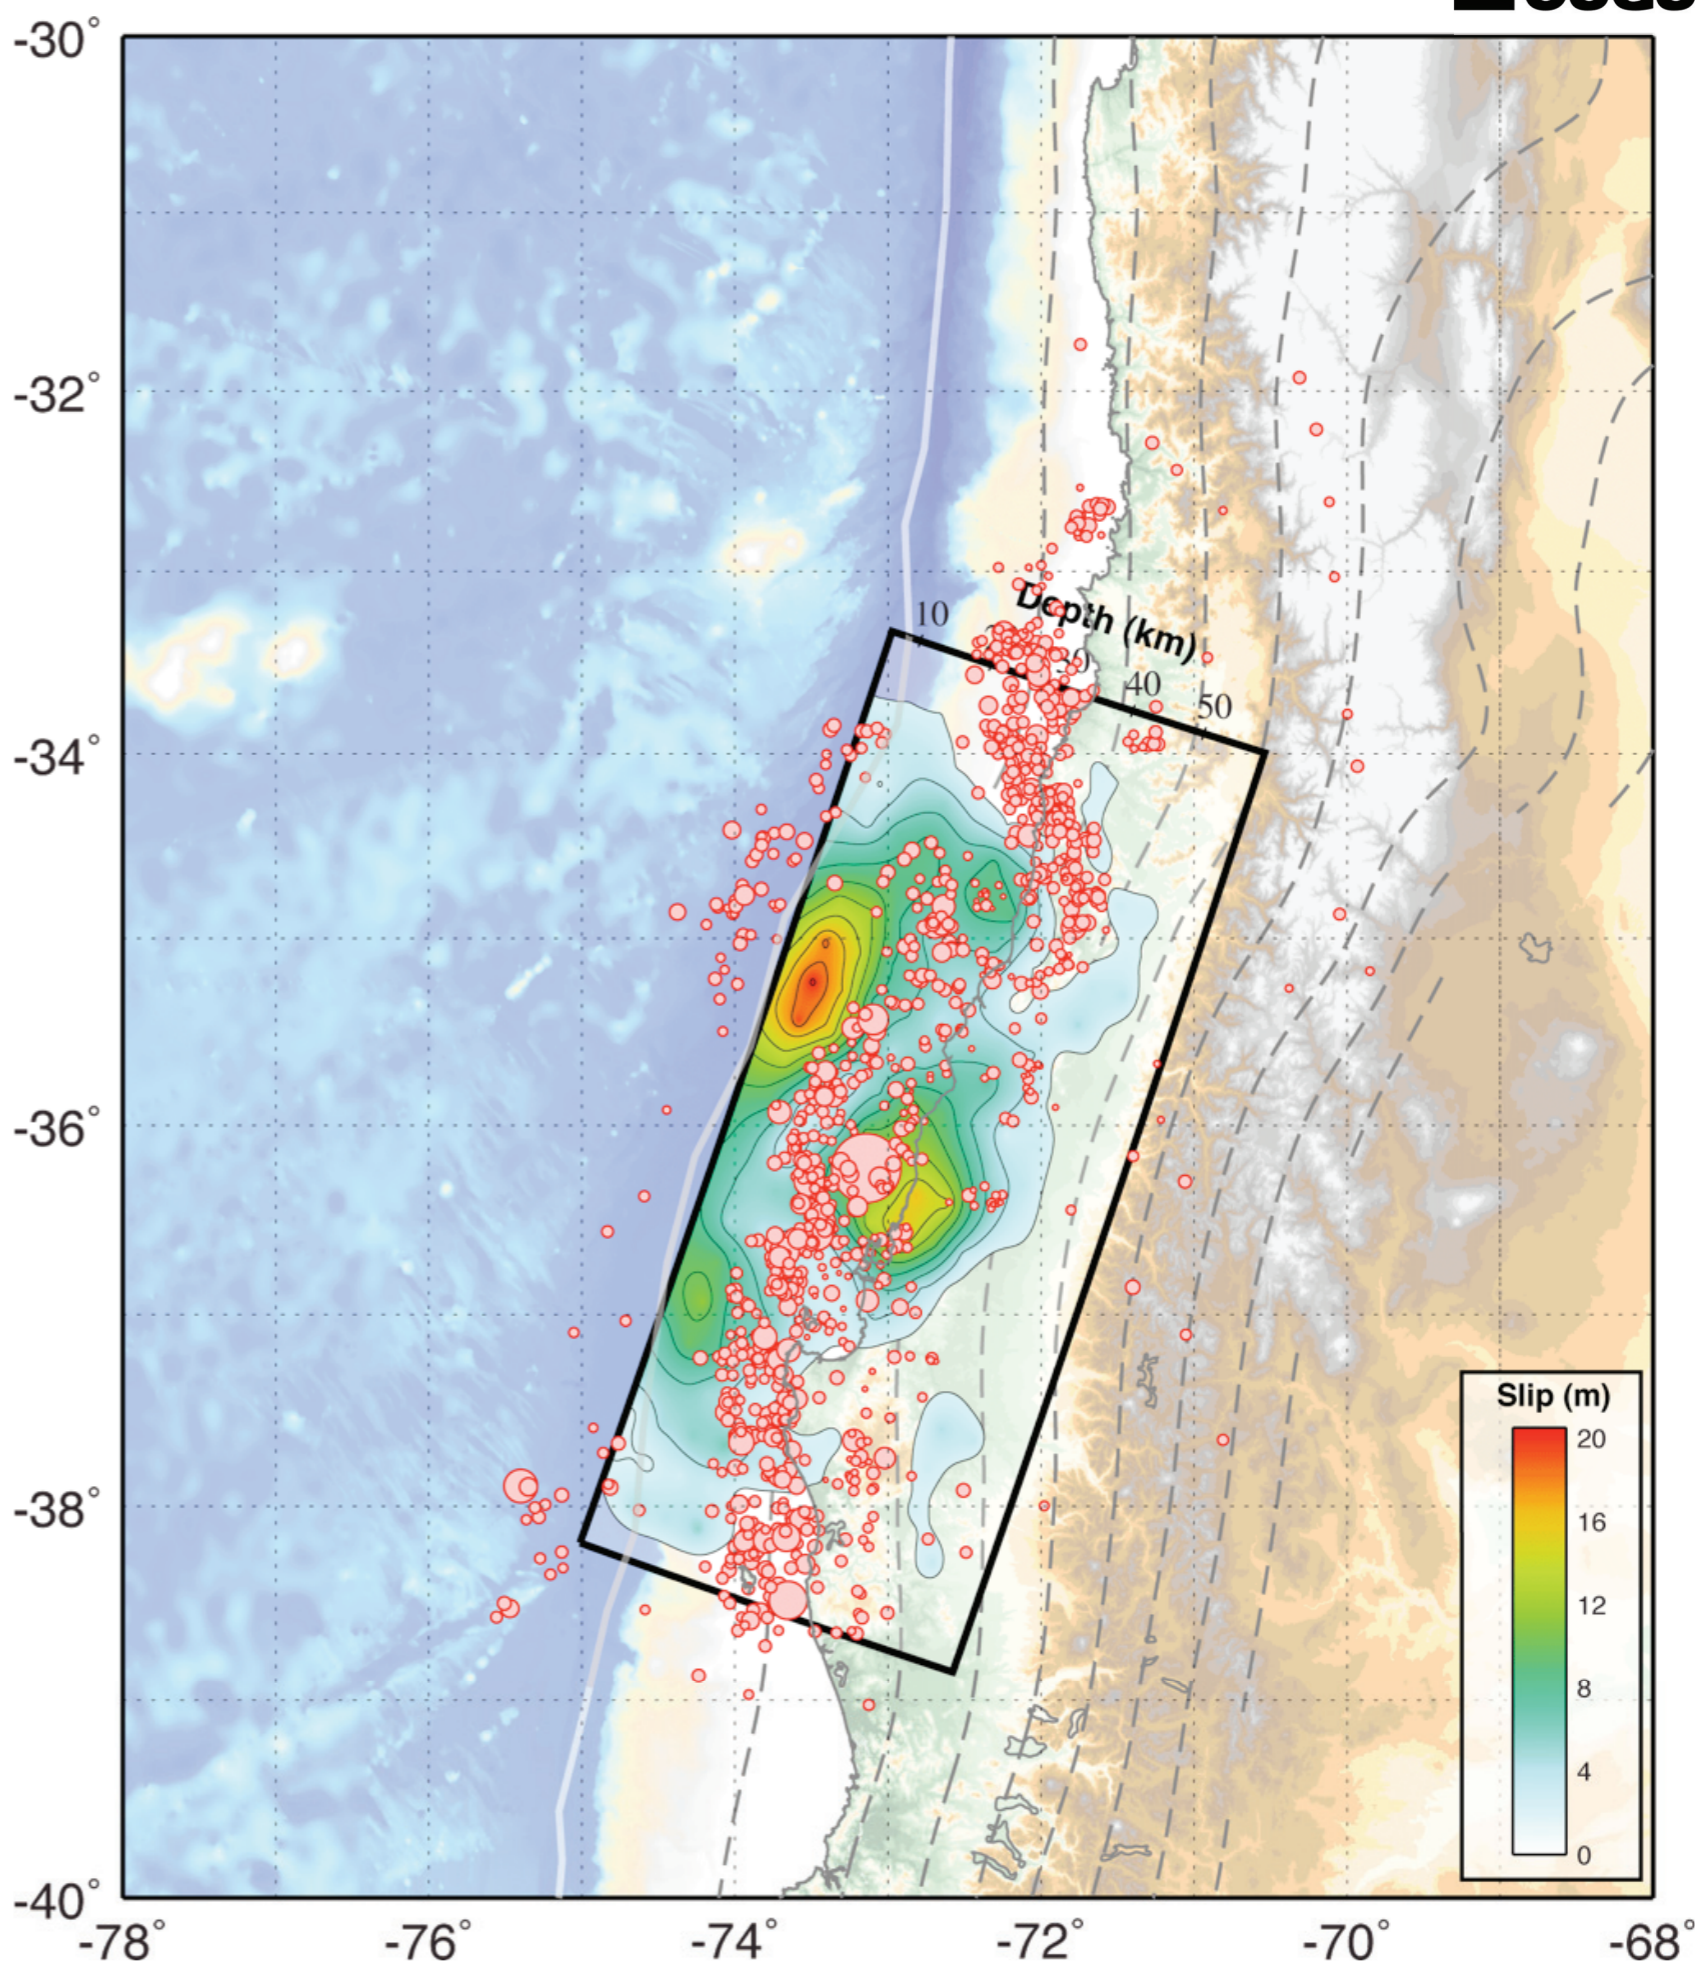

Maule FFM

Single-plane
teleseismic FFM.

Fits seismic data
extremely well
(explains 88% of
waveform data).

Aftershocks
dominantly cluster in
regions of lower or
transitional slip.

Reasonable fits to
horizontal & vertical
GPS data.

Maule FFM

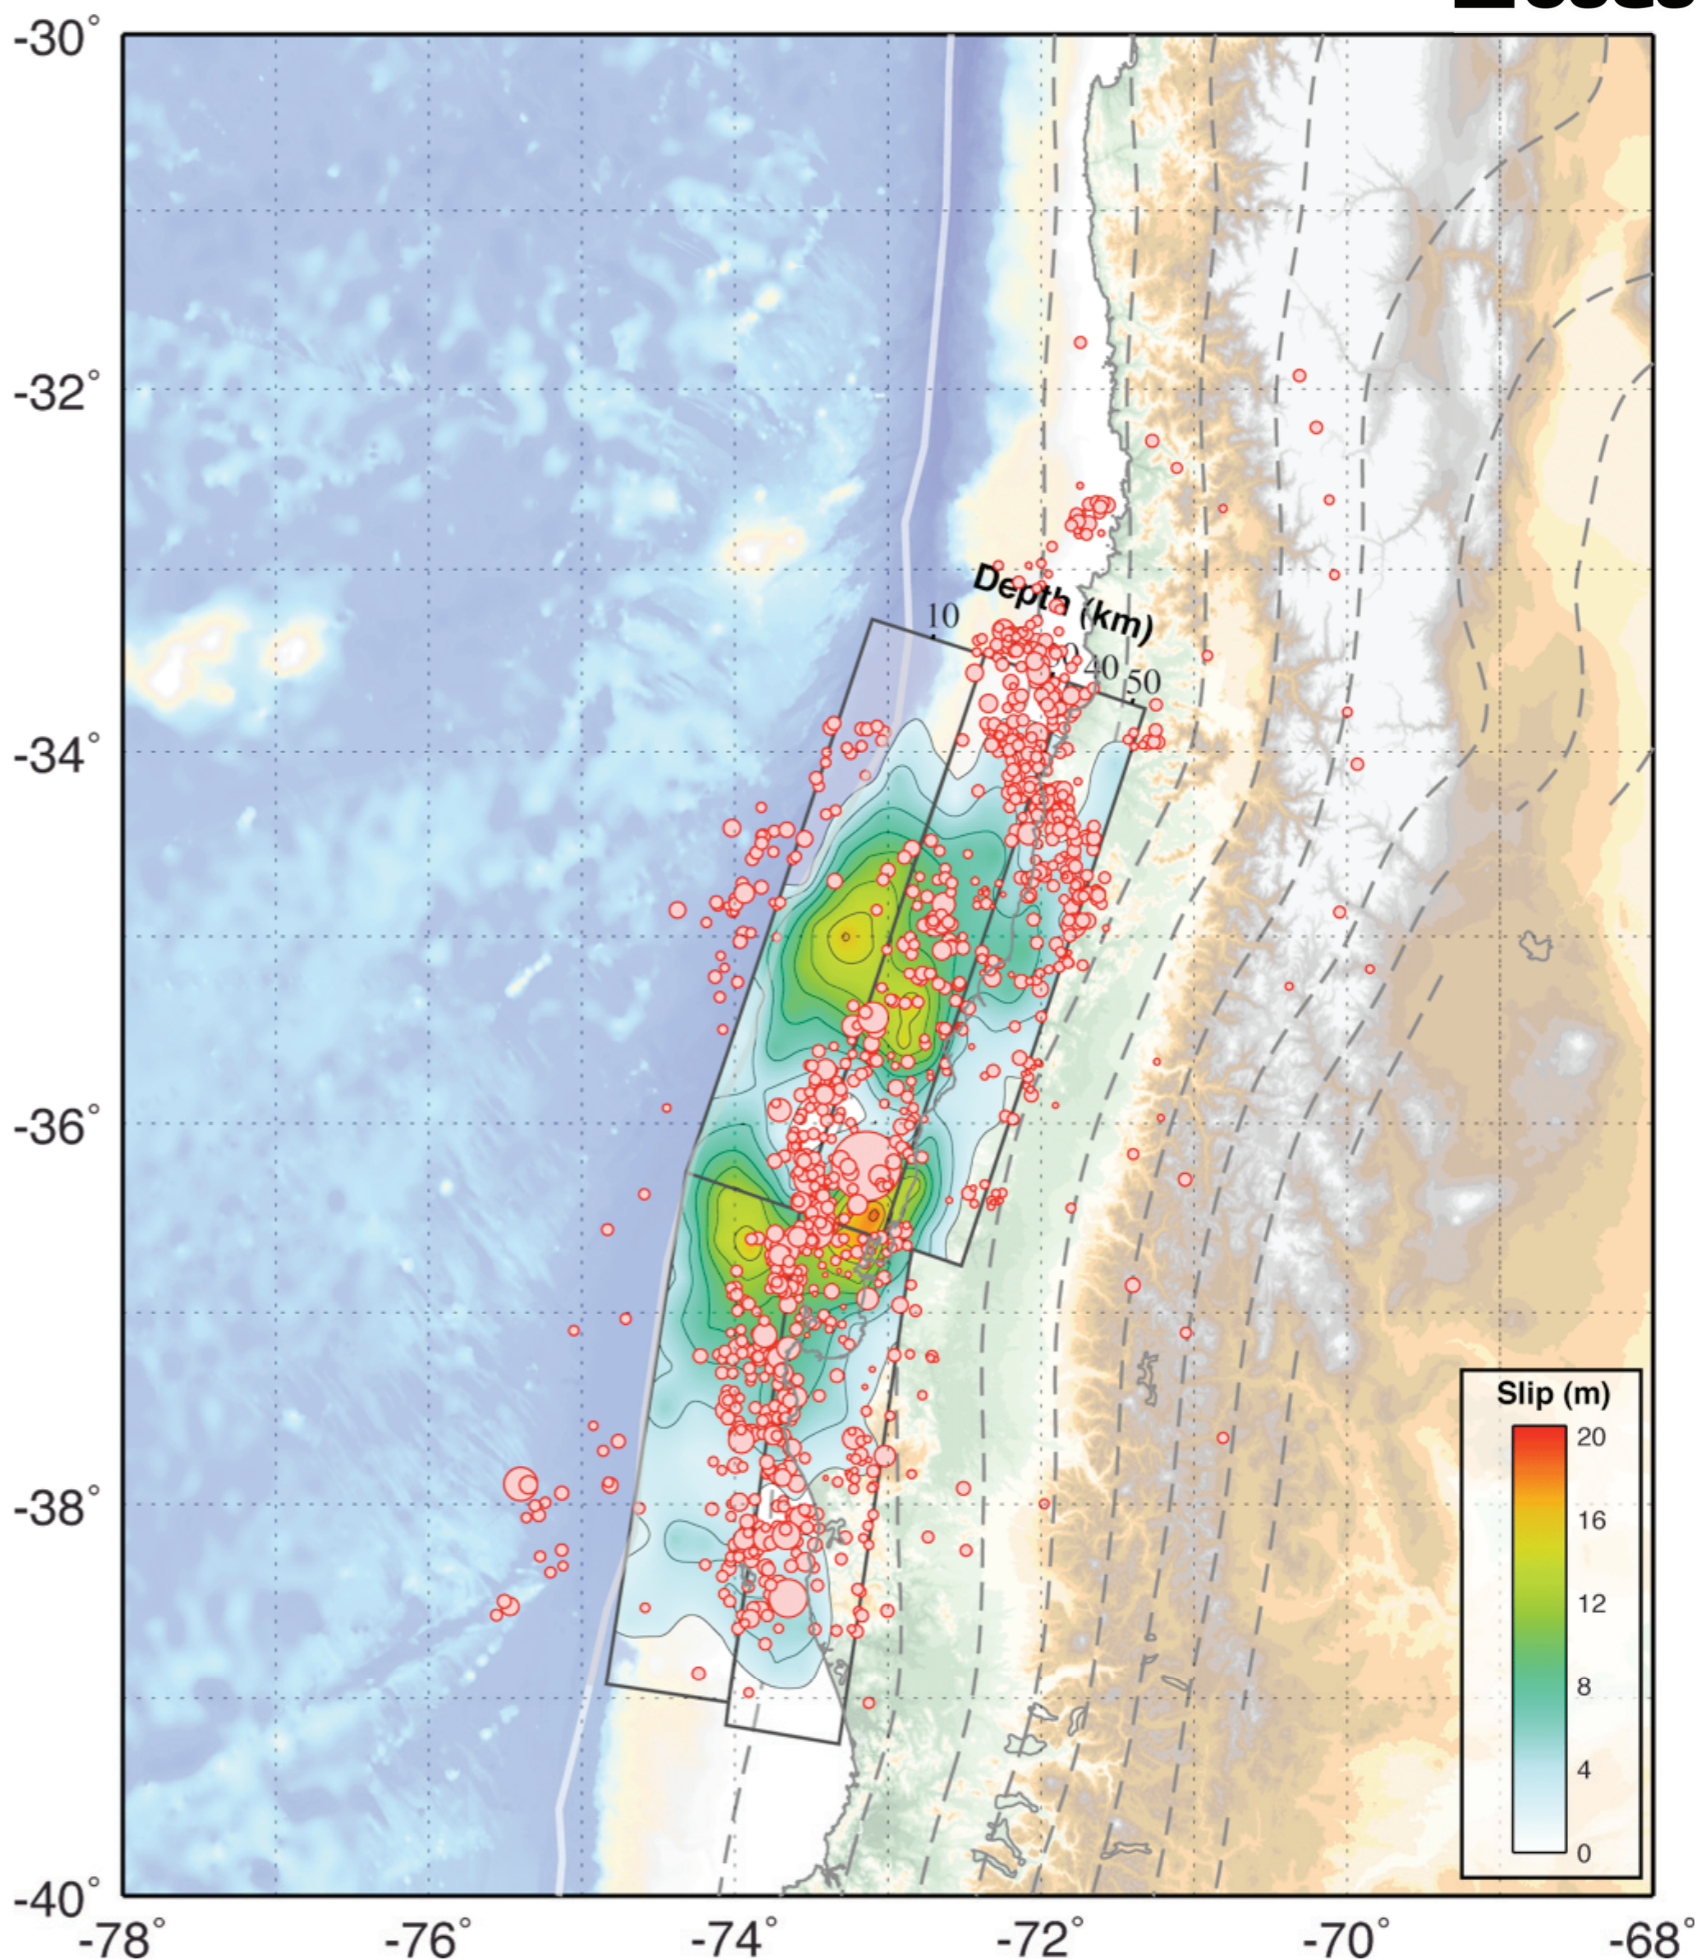

Five-plane
teleseismic FFM.

Better accounts for
down-dip and along-
strike changes in slab
geometry.

Still fits seismic data
extremely well
(explains 90% of
waveform data).

Much better fits to
horizontal & vertical
GPS data.

==> Rapid seismic
FFMs still useful!

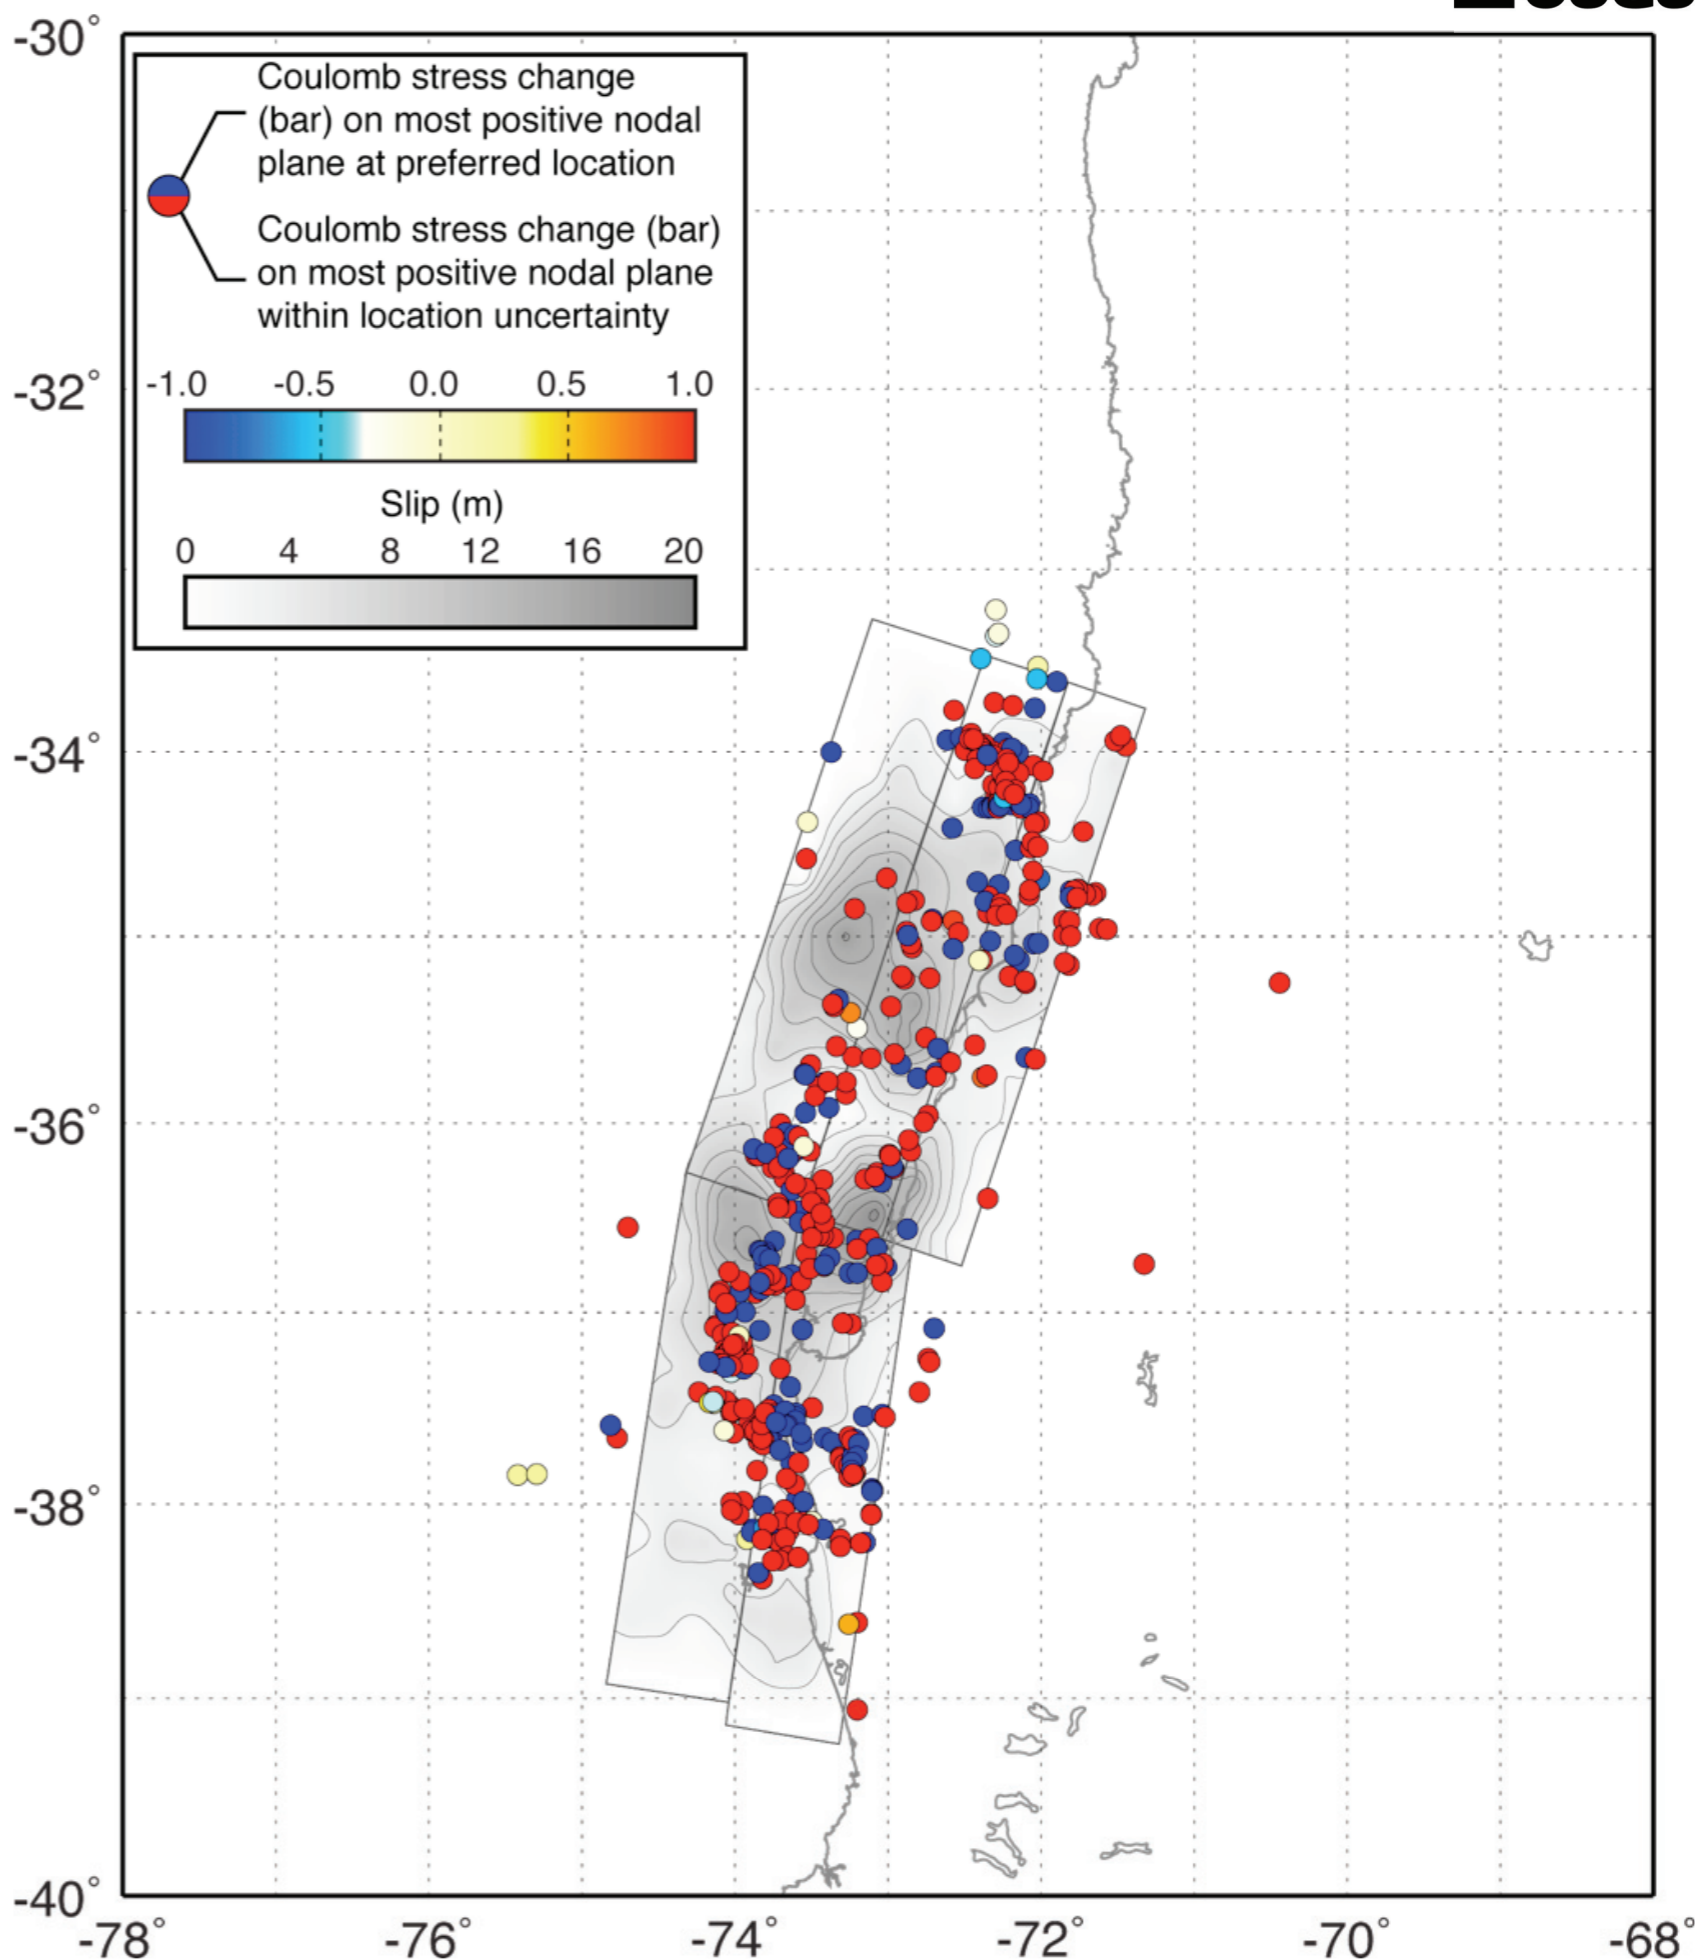

Coulomb Stress Transfer

Δ CFS calculations - comparing favored slip model and aftershock relocations - very sensitive to uncertainties in both.

Preferred locations vs. slip model ==> 55% aftershock nodal planes show + Δ CFS (~5-10% gain over background seismicity).

Within AS uncertainties (a few km), 90% aftershock nodal planes show + Δ CFS (~55% gain over background).

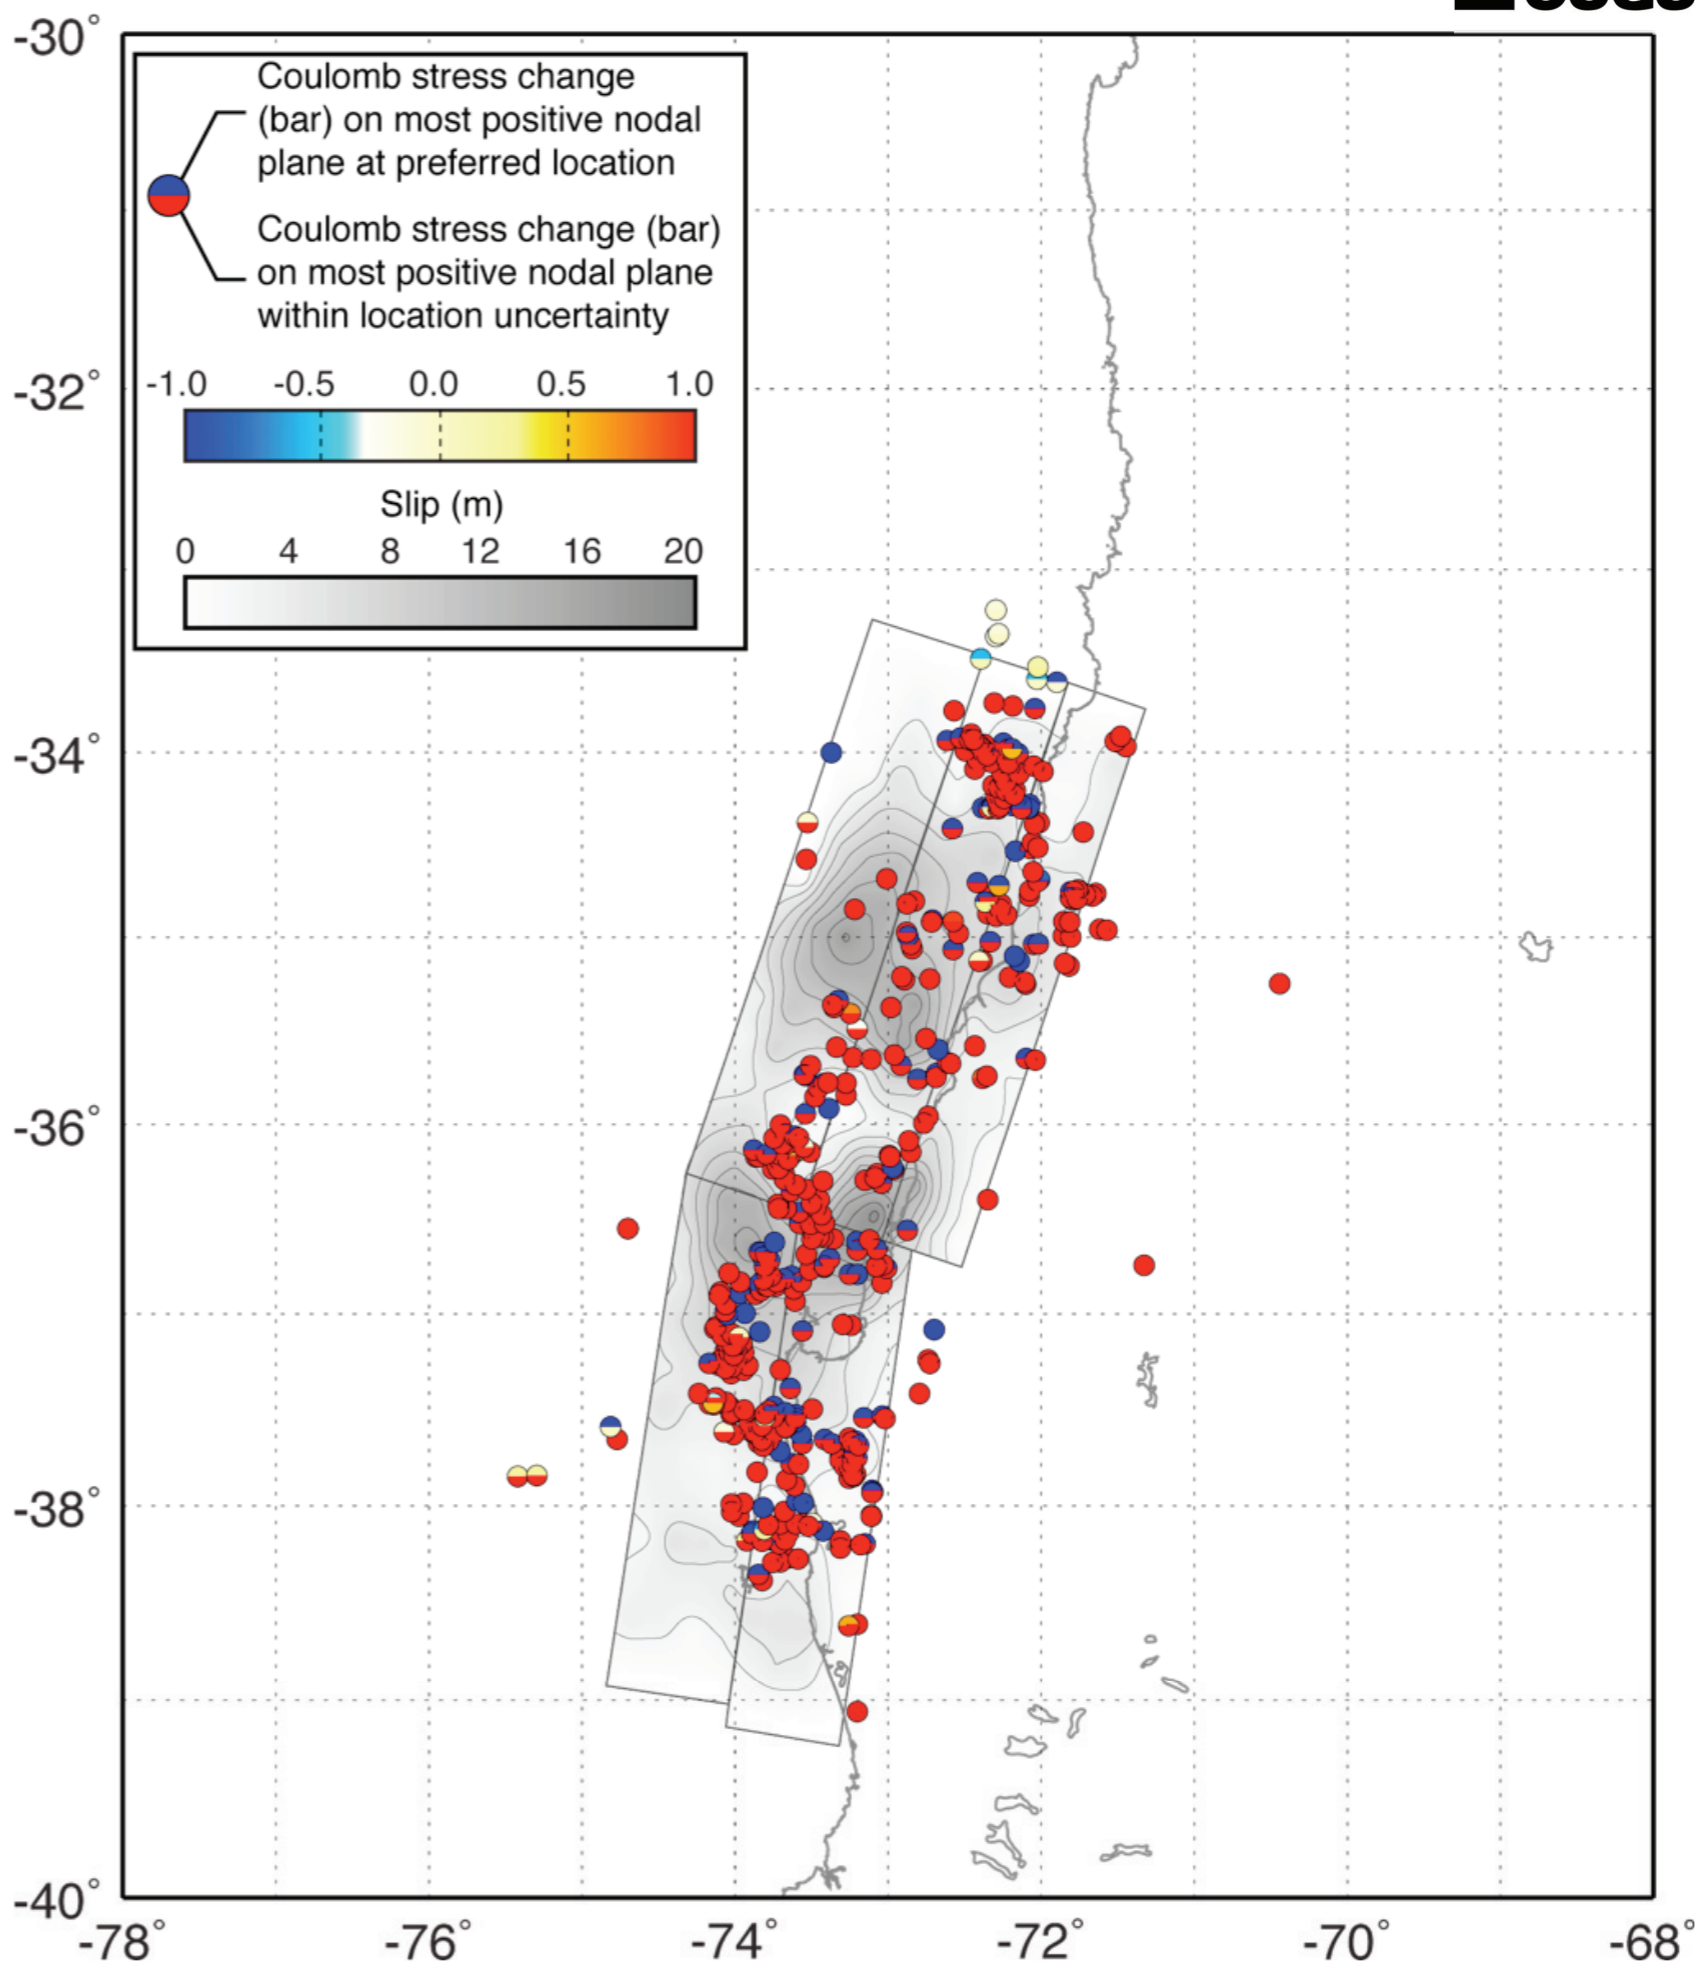

Coulomb Stress Transfer

Δ CFS calculations - comparing favored slip model and aftershock relocations - very sensitive to uncertainties in both.

Preferred locations vs. slip model ==> 55% aftershock nodal planes show + Δ CFS (~5-10% gain over background seismicity).

Within AS uncertainties (a few km), 90% aftershock nodal planes show + Δ CFS (~55% gain over background).

Summary

30,000 aftershocks of the February 2010 Maule earthquake (Mw 8.8) automatically located with an offline module mimicking NEIC's realtime data processing system.

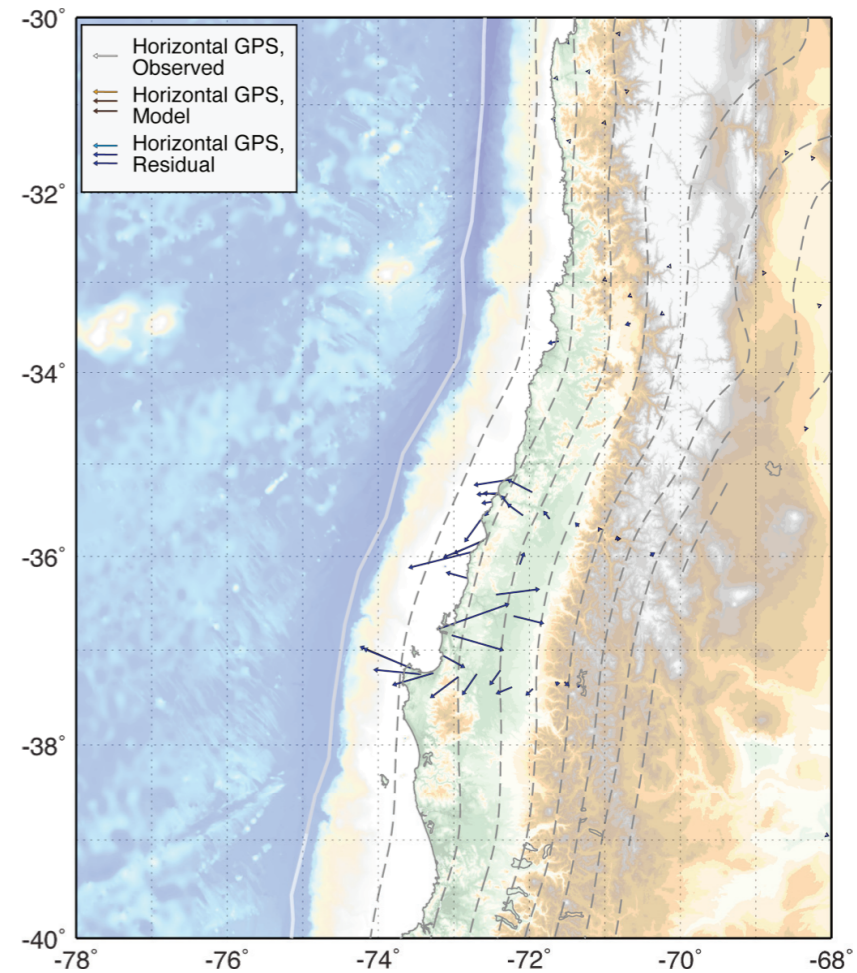

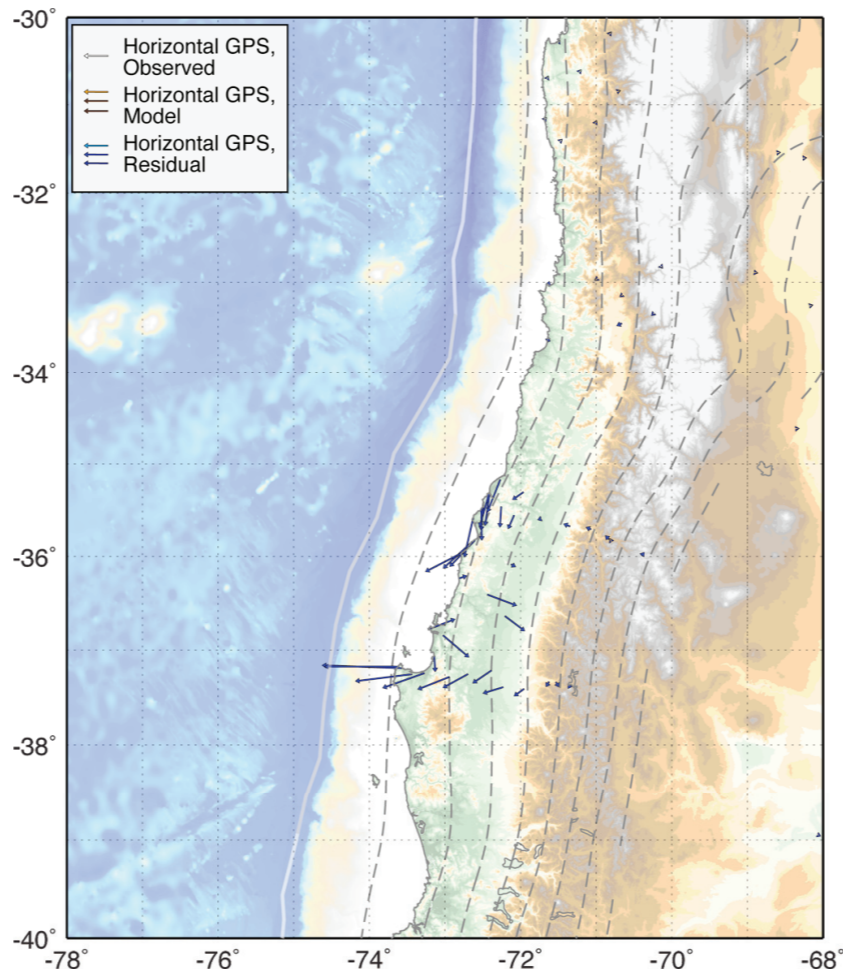

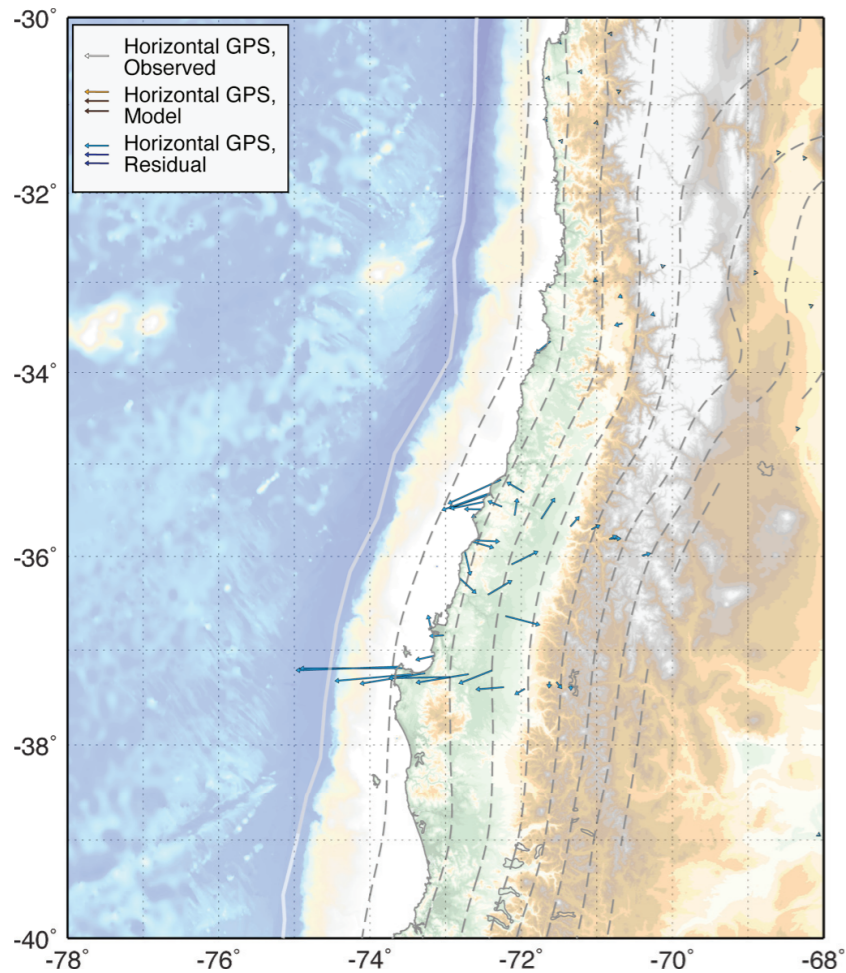

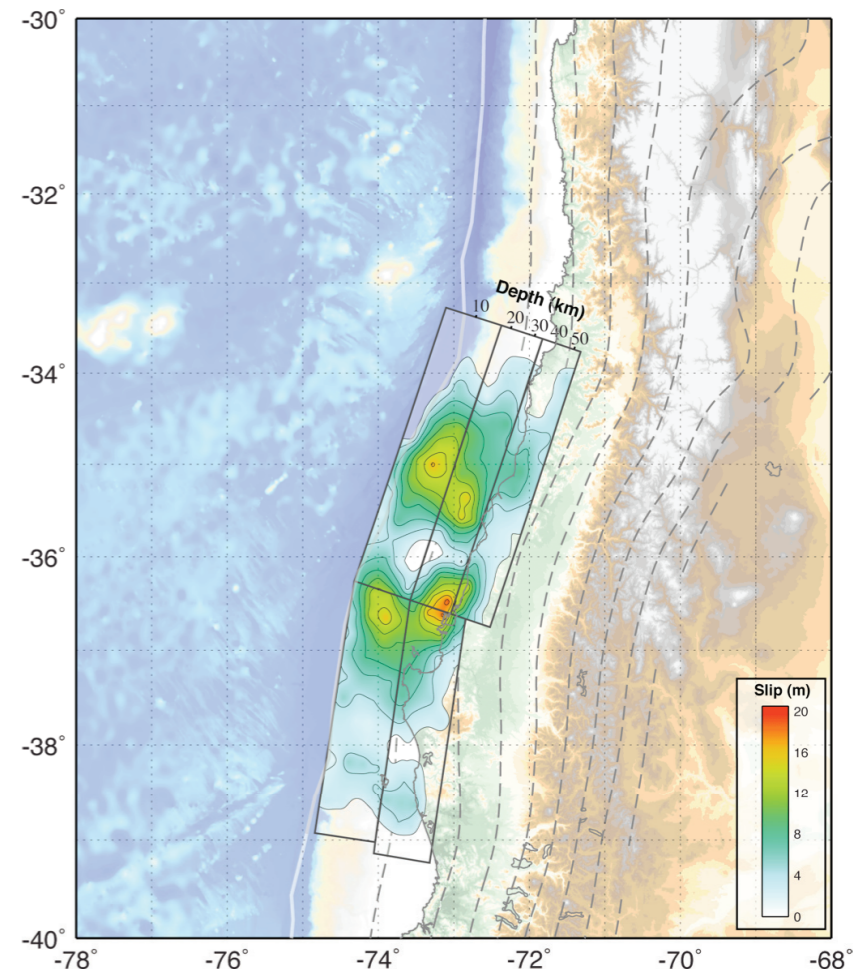

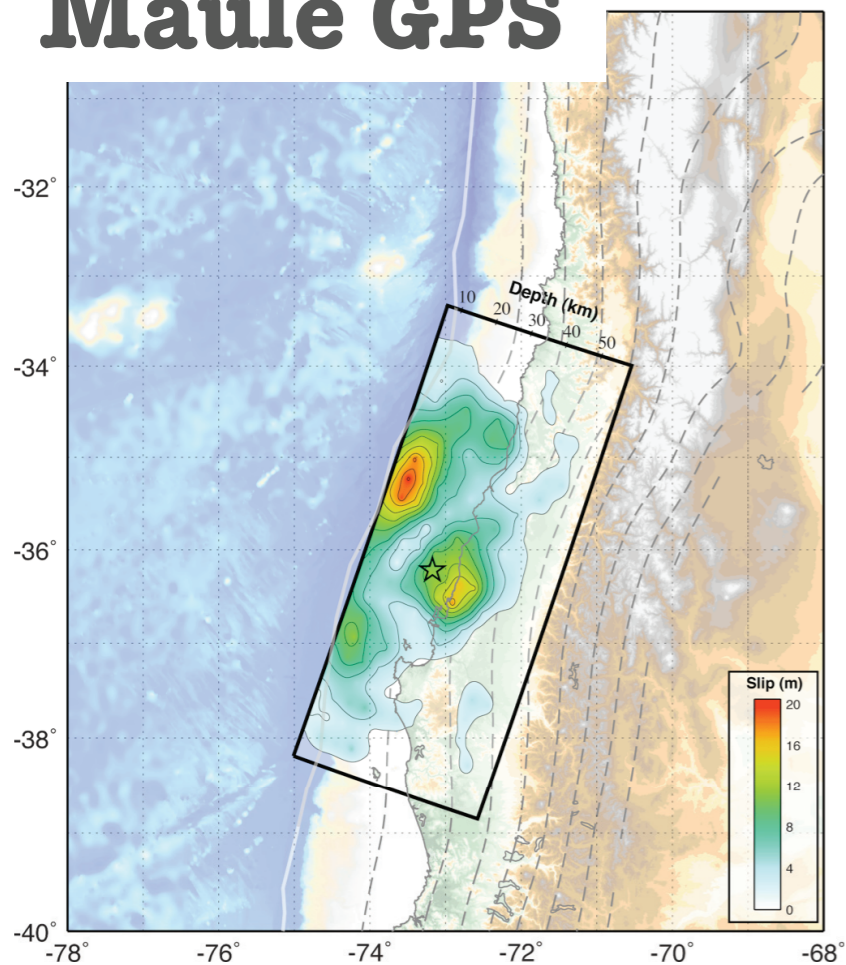

2,500 events relocated to derive a high-precision catalog of the largest aftershocks (uncertainties < 3 km).

500 Regional Moment Tensors allow analysis of tectonics of sequence - EQs divided into upper, lower, interplate. 55% of RMTs are interplate; 35% lower plate. Upper plate aftershocks dominant in north, near Pichilemu, where two large normal faulting aftershocks occurred on 03-11-10.

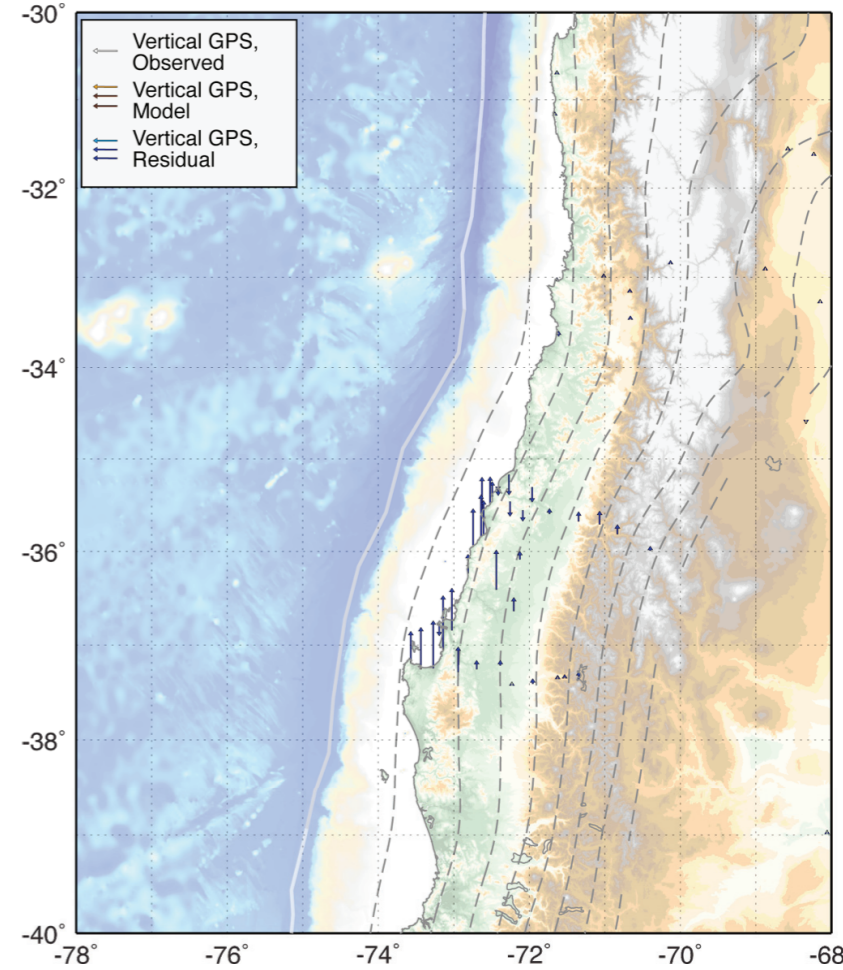

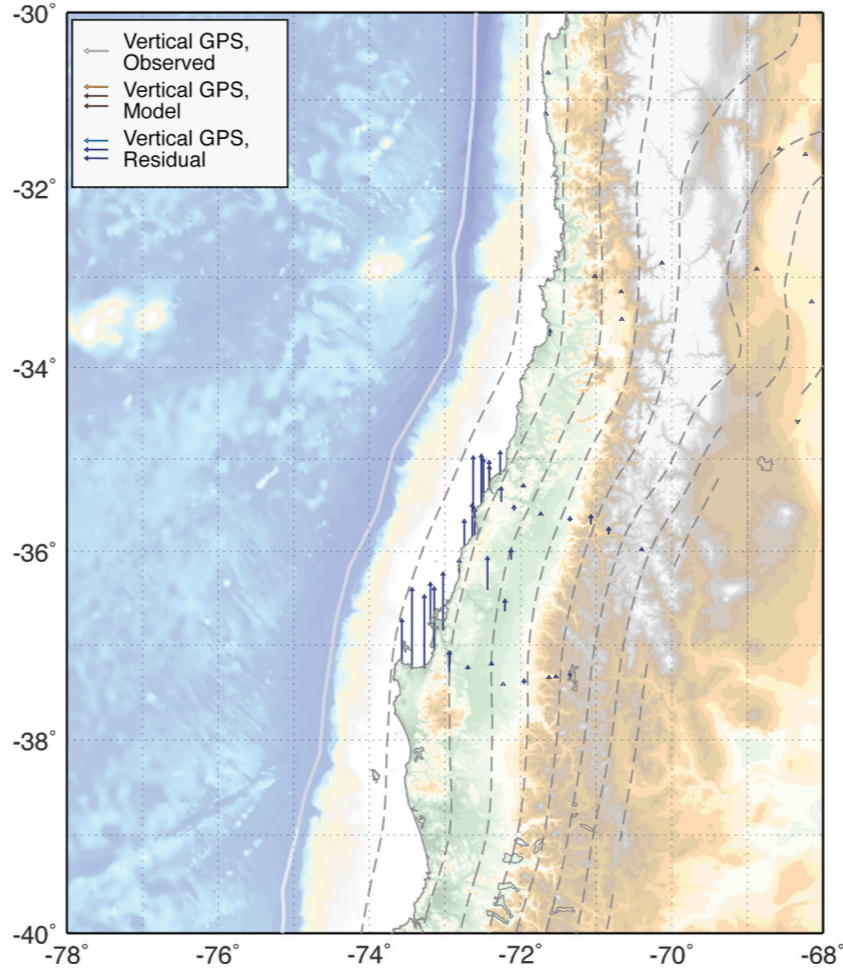

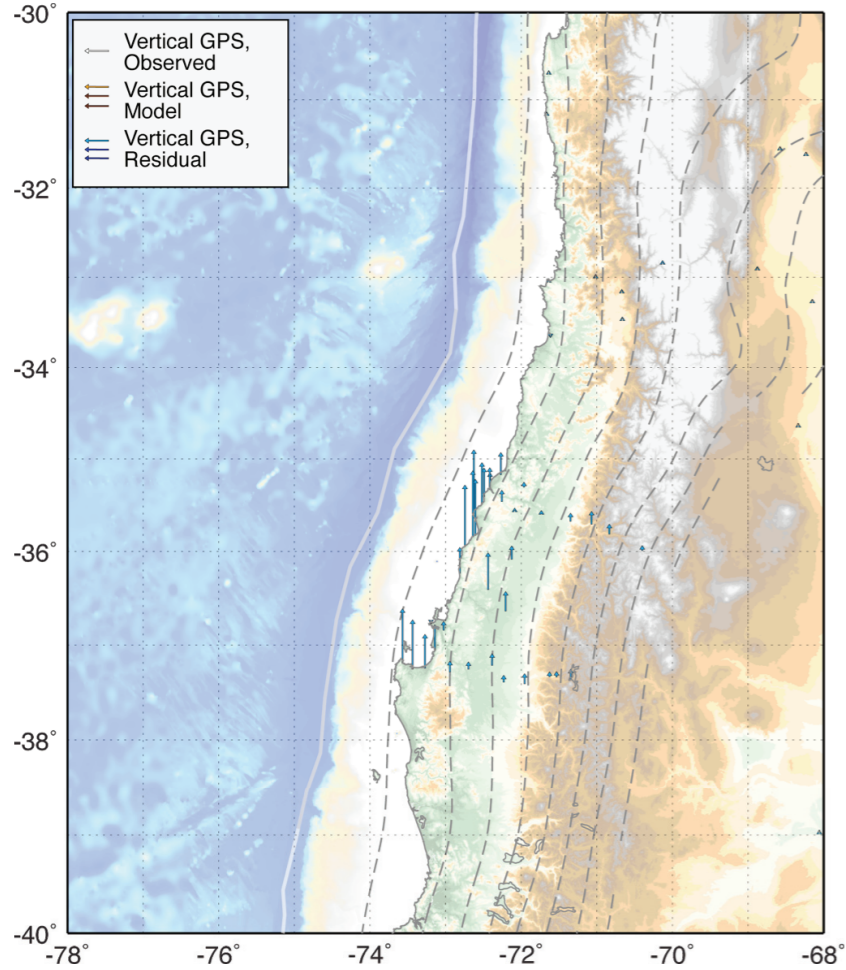

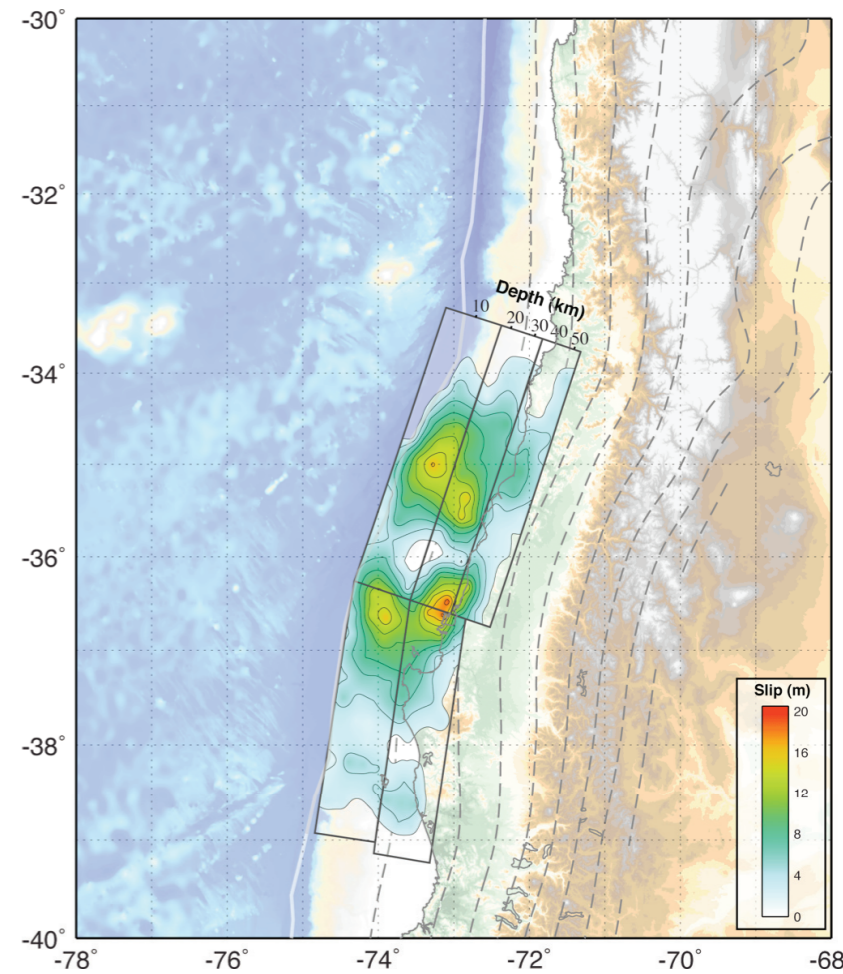

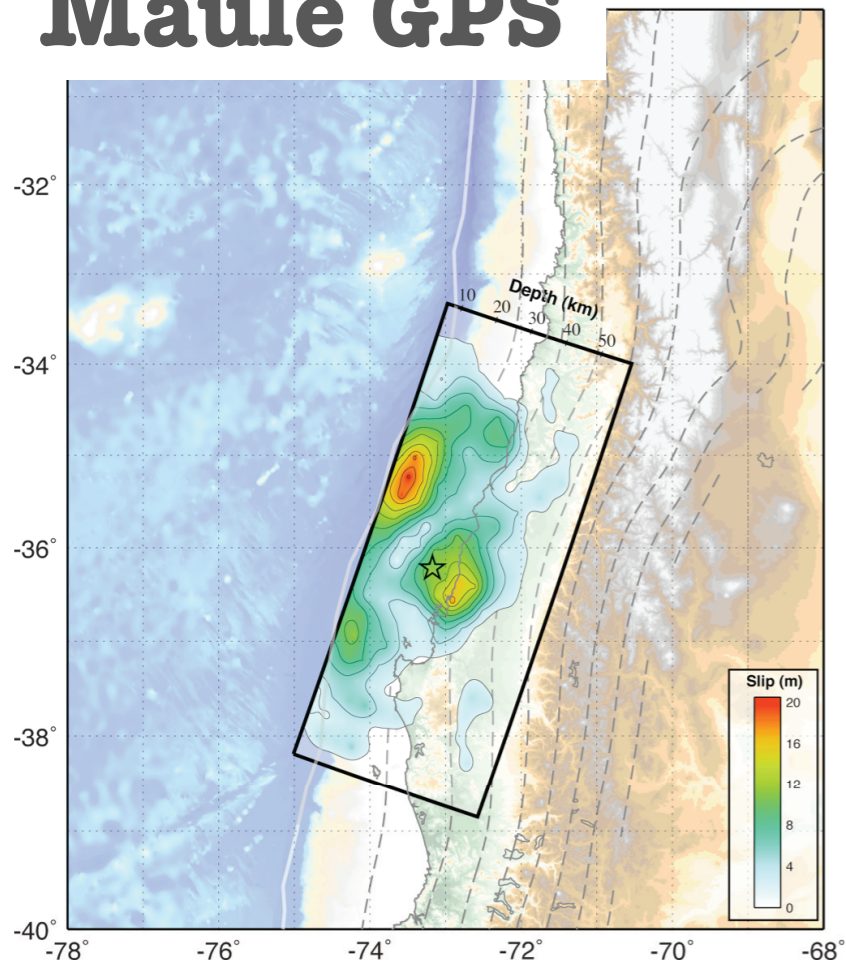

Coulomb stress transfer calculations demonstrate importance of considering uncertainties - in both aftershock locations and slip distribution. Small uncertainties of relocated aftershocks in this study cause the percentage of events occurring on positively stressed faults to increase from 55% (at preferred locations) to 90% (within location uncertainties).

Megathrust Slip VS Slab1.0

FFMs & Slab1.0 - Slip vs Structure

Center = Profile through hypocenter, perpendicular to strike (103°)

M8.8 Maule EQ, 02-27-2010

Comparisons of fault models with subduction zone geometry show coseismic slip was confined to a local minima in the subducting plate.

FFMs & Slab1.0 - Slip vs Structure

Major northern asperity was located on the south side of a local high in subduction zone topography. Hypocenter and southern asperity was within the local minima.
