

## Strain Anomaly History of Yellowstone National Park Constrained by PBO cGPS Measurements

*Huiyu Yang, Meredith Kraner, Heather Turnbull, James Davis, and William Holt*  
*Stony Brook University*

By analyzing the continuous operating PBO horizontal GPS data in Yellowstone area from mid-2013 to the present, we have quantified the development and migration of a large transient strain anomaly. The anomaly begins in August 2013, centered in Norris Geyser Basin (NGB), with the development of a large dilatational strain. The dilatational strain anomaly reached a peak in April, 2014, of  $1.05 \times 10^{-6}$  in the NGB. Peak periods of dilatational strain were accompanied by significant swarms of seismicity, including the largest event since 1980, a magnitude 4.8 on March 30, 2014. In the period following April, 2014 the NGB anomaly began to deflate and a pulse of anomalous positive dilatational strain began to develop within the Yellowstone caldera. On January 6, 2015 the strain in Yellowstone caldera reached a peak anomaly of  $0.55 \times 10^{-6}$ , which persists to the present. The present strain anomaly in Yellowstone Caldera appears to be similar in spatial distribution to the 2004-2006 inflation period described by Chang et al. (2007), but magnitudes are about 50% of the 2004-2006 event.

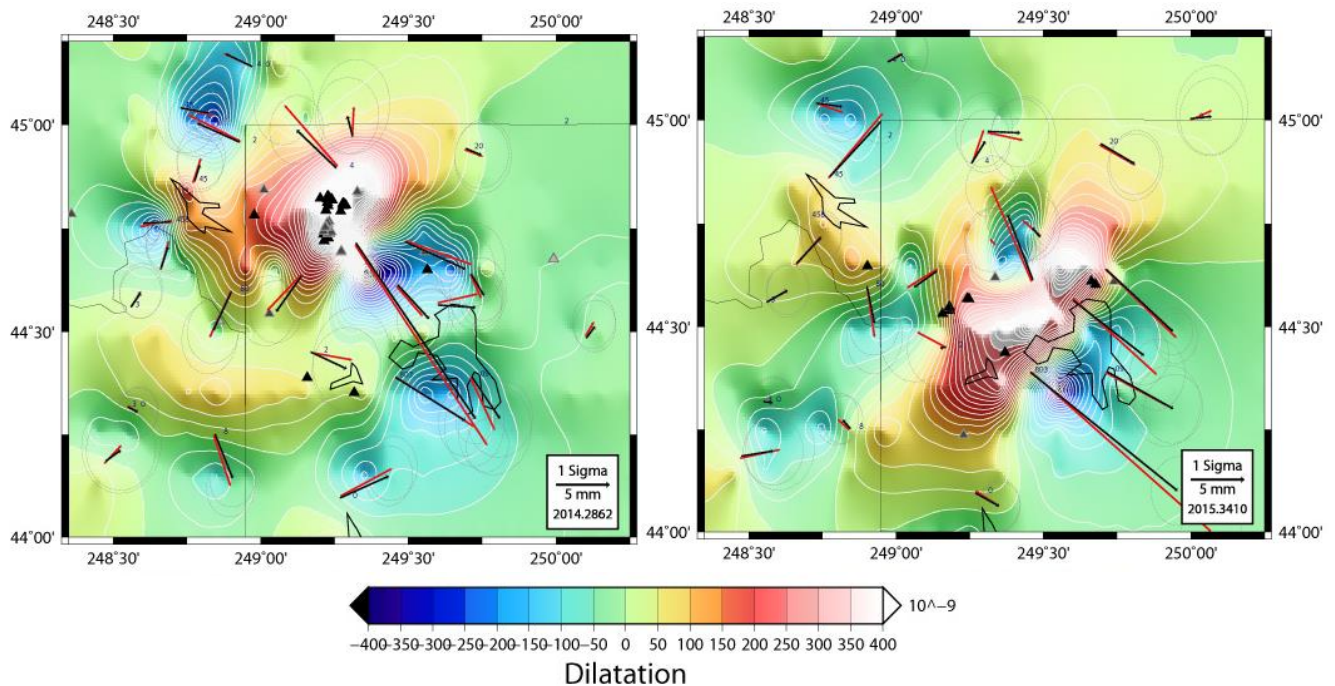

FIGURE: Horizontal dilatational strain anomaly of (left) peak strain in the Norris Geyser Basin in April, 2014 (defined by the interval of motion between June, 2013 – April, 2014) and (right) the strain anomaly at present within Yellowstone Caldera (defined by the interval of motion between June, 2013 – Present). Triangles show earthquakes and depth (black 0-6 km, dark gray 6-12 km, and light gray 12-18 km) that occurred during the two weeks prior to the anomalous strain snapshot.
